I. INTRODUCTION

Interfaces between distinct topological phases of matter [1] support exotic localized wave modes that allow defect-immune, lossless energy transport in various fields of physics, including elasticity, acoustics, quantum mechanics, and electromagnetism. Distinct classes of topological waves have been investigated by establishing analogs with the quantum, spin, and valley Hall effects. We here propose and experimentally demonstrate the possibility of supporting multiple classes of topological modes within a single platform. Starting from a patterned elastic plate featuring a double Dirac cone, we create distinct topological interfaces by lifting such degeneracy through selective breaking of symmetries across the thickness and in the plane of the plate. We observe the propagation of a new class of heterogeneous helical-valley edge waves capable of isolating modes on the basis of their distinct polarization, i.e., the specific mode wave field distribution within the unit cell. Our results show the onset of wave splitting resulting from the interaction of multiple topological equal-frequency wave modes, which may have significance in applications involving elastic beam splitters, switches, and filters.

II. RESULTS

A. Breaking of symmetries allowing for the splitting of topological helical waves

We consider an elastic plate patterned with a periodic array of through-the-thickness circular and triangular holes [4], as shown in Fig. 1(a). The plate is periodic along the directions defined by the \( \mathbf{a}_1 \) and \( \mathbf{a}_2 \) vectors. Its band structure exhibits an isolated double Dirac cone at the \( K \) point as illustrated by the dispersion curves presented in Fig. 1(d). The Dirac cones arise as a result of the \( D_{3h} \) symmetry of the structure, i.e., consisting of \( C_3 \) (threefold rotational) symmetry, \( \sigma_h \) symmetry (or reflection symmetry about the midplane of the plate), and \( \sigma_v \) symmetry (or inversion symmetry about a plane normal to the midplane of the plate and along the lattice vectors).
Starting from this configuration, geometric perturbations are introduced so to break the $\sigma_h$ and $\sigma_v$ symmetries, and produce nontrivial band gaps that respectively support helical and valley modes in a common frequency range. Specifically, we break the $\sigma_v$ symmetry by replacing the through holes with blind holes of height $h$, as shown in Fig. 1(b). We denote the configuration with the blind holes on the top (bottom) surface as $H^+$ ($H^-$). This geometric perturbation causes modes spanning the two Dirac cones to hybridize in analogy with the spin-orbital coupling interaction in QSHE, which breaks the degeneracy and opens a topological band gap [Fig. 1(e)]. The interface between structures supporting $H^+$ ($H^-$) and $V^+$ ($V^-$) unit cells, respectively. The plate with through holes is characterized by a double degenerate Dirac point visible in (d), while the cases of $H^+$ ($H^-$) (e) and $V^+$ ($V^-$) (f) feature a complete band gap (light gray rectangle) centered at approximately 102 kHz. The widths and center frequency of the band gaps are matched by selecting the partial depth of the blind holes $h$ in the $H^+$ ($H^-$) configuration ($h = 0.91H$ for the band diagram shown), and the radii $r$ and $R$ of the through holes in the $V^+$ ($V^-$) case ($r = 0.51R$ for the diagrams shown). Refer to Appendix A for details on band structure calculations.

The existence of the above mentioned hybrid HV edge modes is verified through the computation of the band structure of finite strips including a total of 20×1 unit cells, with periodicity conditions imposed along the $a_1$ direction and free boundaries along $a_2$ (see the Appendixes for details on computations). Results are reported in Figs. 2(a), 2(c), and 2(e), where the bulk modes are shaded in gray, while the edge states are denoted by the black, blue, and red circles for the $I(H^+, H^-)$, $I(H^+, V^R)$, and $I(H^-, V^-)$, respectively. The additional notation of the indexes +/− for the modes keeps track of their different group velocity with respect to the direction of propagation. As noted above, two edge modes $\Phi^{±}$ are supported by the $I(H^+, H^-)$ interface, while...
FIG. 2. Nontrivial interfaces: band structures and edge states. (a), (c), and (e) Dispersion diagrams for the nontrivial waveguides defined by $\mathcal{I}(H^+, H^-)$, $\mathcal{I}(H^+, V^R)$, and $\mathcal{I}(H^-, V^r)$ interfaces. The band structures are computed considering a $20 \times 1$ $a_1$-periodic strip (10 unit cells on each side of the domain wall). The bulk modes are reported as gray square dots while the interface modes in black, blue, and red square dots, respectively. The edge modes are denoted by the index $+(-)$ according to the positive (negative) group velocity relative to the propagation direction. (b), (d), and (f) Corresponding eigenvectors [colors represent magnitudes of the absolute normalized displacement, varying from zero (blue) to maximum (red)] show mode localization at the interface (the deformation for only six cells is reported for the clarity of representation). The close-ups of the mode shapes (rainbow scale) clearly illustrate the connection between the two helical edge states $\Phi^+$ and $\Phi^-$ existing at the $\mathcal{I}(H^+, H^-)$ interface and those at $\mathcal{I}(H^+, V^R)$ and $\mathcal{I}(H^-, V^r)$ interfaces, $\Psi^+$ and $\Psi^-$ respectively, in terms of normalized out-of-plane displacement field distribution. The different displacement distribution of the modes at the interfaces suggests the possibility of selective mode excitation. The selective mode excitation can be achieved by assigning a displacement field into specific regions of the unit cell where one mode (for instance $\Psi^+ / \Phi^+$) exhibits large amplitude displacement while the other one ($\Psi^- / \Phi^-$) is characterized by an almost zero displacement. For the $\Psi^+$ and $\Psi^-$ modes, the distribution of phases (positive in blue and negative in red) is reported as well.
a single mode exist at the HV interfaces: $\Psi^+ \text{ and } \Psi^-$ for $\mathcal{I}(H^+, V^R)$ and $\mathcal{I}(H^-, V^r)$, respectively.

**B. Numerical and experimental observation of equal-frequency splitting**

A domain wall formed according to each of the three interfaces considered, i.e., $\mathcal{I}(H^+, H^-)$, $\mathcal{I}(H^+, V^R)$, and $\mathcal{I}(H^-, V^r)$, separates two phases in the middle of the strip. Let us consider the two edge waves that initially propagate along the $\mathcal{I}(H^+, H^-)$ interface and subsequently encounter two $\mathcal{I}(H, V)$ interfaces, each supporting a single HV mode with distinct polarization. At the y-shaped junction, each wave follows the interface that matches its polarization, thus causing the two wave modes to split. This is possible under the condition that the frequencies for the three edge states match. To ensure this, the band gaps of the $H$ and $V$ lattices are designed to occur in a common range of frequencies highlighted by the gray rectangles in Figs. 1(e) and 1(f) which is achieved by properly selecting the geometric perturbations that produce the distinct topological phases. Specifically, the results for the $H$ phase [Fig. 1(e)] correspond to a blind hole depth $h = 0.91H$, with $H$ denoting the plate thickness, while the $V$ phase results [Fig. 1(f)] are obtained for $r = 0.51R$.

Numerical evaluations of the mode shapes at point C [Fig. 2(c)] and D [Fig. 2(e)], shown in Figs. 2(d) and 2(f), respectively, for the two interfaces, confirm the localized nature of the modes and reveal their distinct distribution of the displacement magnitude and phase along the interface (see the zoomed-in plots). The magnitude displacement and phase plots suggest the possibility of selective modal excitation by applying an input at the locations shown in the figures, which highlight the spatial separation of the maximum amplitude points for the two modes. For example, preferential excitation of mode $\Psi^+$ ($\Psi^-$) could be achieved by injecting a perturbation at locations where the motion of the interface unit cells is high, and where the displacement for the other mode $\Psi^-$ ($\Psi^+$) is small [see zoomed-in views in Figs. 2(d) and 2(f)]. To confirm the splitting of the topologically protected helical waves, we designed and fabricated a waveguide made of 35 (in the $a_1$ direction) × 25 (in the $a_2$ direction) unit cells hosting the three different domains $H^+$ (blue boundary), $H^-$ (green boundary), and $V$ (red boundary), as shown in Fig. 3(a). These domains are separated by three interfaces: $\mathcal{I}(H^+, H^-)$, $\mathcal{I}(H^+, V^R)$, and $\mathcal{I}(H^-, V^r)$. Such an arrangement is chosen to illustrate the ability of the waveguide to split the two helical waves ($\Phi^+$ and $\Phi^-$) at the y-shaped junction. The plate is made of aluminum and the unit cell lattice parameter is $a = 20.5 \text{ mm}$.

First, numerical simulations are conducted to evaluate the distinct propagation patterns followed by the edge modes along the interfaces, depending on the selective mode excitation. A finite element (FE) model for the finite plate shown...
in Fig. 3(a) is implemented in ABAQUS. Calculations are conducted in the frequency domain. Elastic waves are excited by imposing an out-of-plane harmonic excitation at half of the \( I(H^+, H^-) \) interface [white dot in Figs. 3(c) and 3(d)] according to the \( \Psi^+ \) and \( \Psi^- \) configurations presented in Figs. 2(d) and 2(f). The frequency content of the excitation is set to 98 kHz, so to prevent the excitation of bulk modes. The connection between the two helical edge states \( \Phi^+ \) and \( \Phi^- \) existing at the \( I(H^+, H^-) \) interface and those at \( I(H^+, V^R) \) and \( I(H^-, V^-) \) interfaces, \( \psi^+ \) and \( \psi^- \), respectively, is given by the similar displacement distribution existing between (i) \( \Phi^+ \) and \( \Psi^+ \) and (ii) \( \Phi^- \) and \( \Psi^- \) [compare the close-ups of Fig. 2(b) and those of Figs. 2(d) and 2(f)]. This implies that when a specific mode, excited at the \( I(H^+, H^-) \) interface (\( \Phi^+ \) or \( \Phi^- \)), reaches the \( y \)-shaped junction, it will trigger the \( \Psi^+ \) or \( \Psi^- \) mode, respectively, according to its mode shape. If both \( \Phi^+ \) and \( \Phi^- \) modes are excited at the \( I(H^+, H^-) \) interface, both \( \psi^+ \) and \( \psi^- \) will be generated at the \( y \)-shaped junction. The resulting distribution of the von Mises stress fields, reported in Figs. 3(c) and 3(d), clearly show that when the wave reaches the \( y \)-shaped junction it follows either the \( I(H^+, V^R) \) or \( I(H^-, V^-) \) interface depending on the initial type of input. In both cases, weak penetration inside the bulk region is observed. Refer to the Supplemental Material (SM) [37] for additional transient dynamic simulations.

The splitting of these modes is then demonstrated experimentally testing the plate [Fig. 3(a)] by means of a scanning laser Doppler vibrometer (SLDV). The SLDV measures the out-of-plane velocity component of the motion of the plate \( \mu \) of 800 \( \mu \)s. These wavenumbers are highlighted by the red and black circles of different radii in Fig. 4(c), and correspond to the two wavenumber values associated with modes \( \psi^+ \) and \( \psi^- \), respectively. The contribution of the two modes to the wave field of Fig. 4(f) can be effectively separated through wavenumber filtering in reciprocal space [38]. To this end, the 2D-FT for the wave field is masked by 2D Gaussian windows (see the Appendices) centered at \( k_1 \) and \( k_2 \), whose application leads to the filtered 2D-FT in Figs. 4(d) and 4(e) showing the two separated modes. Inverse 2D-FT transformation in physical space provides the decoupled contributions to the wave field shown in Figs. 4(g) and 4(h). From these figures it clearly emerges that when the two rightward-propagating helical modes \( \Phi^+ \) and \( \Phi^- \) [Fig. 2(a)] reach the \( y \)-shaped junction, they split and respectively follow the \( I(H^+, V^R) \) and \( I(H^-, V^-) \) interfaces as \( \psi^+ \) and \( \psi^- \) modes on the basis of their polarization. The need of the post-processing derived from the fact that an \textit{ideal} selective mode excitation can only be achieved by assigning a displacement field into specific regions of the unit cell where one mode (for instance \( \psi^+ \)) exhibits large amplitude displacement while the other one (\( \psi^- \)) is characterized by an almost zero displacement [refer to red and blue colors, respectively, of the close-ups shown in Figs. 2(d) and 2(f)]. However, given (i) the chosen unit cell dimension (\( a = 20.5 \) mm) and (ii) the magnitudes of the displacement distribution of \( \psi^+ \) and \( \psi^- \) [see Figs. 2(d) and 2(f)], a single mode could only be excited if the excitation distribution is limited over an area of maximum 2 mm\(^2\). While this can be (and indeed has been) achieved in numerical models [see Figs. 3(c) and 3(d)], where displacements can be assigned to single mesh nodes, in the experiments the dimension of realistic piezoelectric transducers (12-mm diameter) capable of generating elastic guided waves on an approximately 6-mm-thick aluminum plate did not allow such
FIG. 4. Experimental observation. (a) Spatiotemporal 2D-FT of 1D line scans along interfaces $I(\mathbf{H}^+ , V^R)$ and $I(\mathbf{H}^-, V^-)$. Color maps show normalized 2D-FT amplitudes, superimposed to the numerically predicted band structure (white square dots) highlighting the $\Psi^+$ (left panel) and $\Psi^-$ (right panel) modes. (b) Measured wave field for the $\Psi^+$ and $\Psi^-$ propagating edge modes displaying opposite spins profiles, as highlighted by the superimposed black arrows. The measurements correspond to the area denoted as “2D local scan regions” in Fig. 2(b). Time animations of the measured wave fields are provided in the SM [37]. (c) Spatial 2D-FT for a representative snapshot ($t = 1120\mu s$) of the (f) wave field recorded over the area denoted as “2D scan region” in Fig. 3(b). The 2D-FT highlights the presence of a pair of diffraction peaks defined by the concentration at contour levels in the reciprocal space $k_x, k_y$, which are associated with wavenumbers $k_1 = 60$ rad/m (red circle) and $k_2 = 80$ (black circle) rad/m, corresponding to the distinct modes of propagation $\Psi^+$ and $\Psi^-$. (d) and (e) Filtered 2D-FTs with isolated modes and (g) and (h) corresponding propagation in physical space showing the decoupled wave fields and distinction propagation paths for the two separated modes.

III. DISCUSSION

In conclusion, we proposed and experimentally tested a platform that supports multiple classes of topological modes. In the proposed configuration, implemented on a patterned plate, topologically nontrivial gaps are obtained by creating interfaces between material phases that selectively break spatial inversion symmetries. Through engineering of the nontrivial gaps, the considered system is capable of splitting purely topological protected helical edge waves into heterogeneous helical-valley modes on the basis of the initial polarization. The results presented herein, both numerical and experimental, provide fundamental insights in the behavior of topologically protected edge modes in elastic systems, and suggest new avenues for topologically protected wave transmission that may be extended to other physical domains, such as acoustics, and photonics. The findings of this study have direct

a localized excitation, implying a simultaneous excitation of both $\Psi^+$ and $\Psi^-$ modes.
implications for applications where selective waveguiding, or the isolation and control of vibrations are ultimate goals, as in civil, mechanical, and aerospace engineering structures. Also, the wave mode selection capabilities of the considered interfaces and y-shaped junction may be of significance for the transmission of information through elastic or acoustic waves as, for example, in the case of surface acoustic wave (SAW) devices.

The data that support the plots within this paper and other findings of this study are available from the corresponding author upon request.

APPENDIX A: SIMULATIONS

Dispersion diagrams and mode shapes presented in Figs. 1(d)–1(f) and Fig. 2 are computed using Bloch-Floquet theory in full 3D FEM simulations carried out via the finite element solver COMSOL Multiphysics. Full 3D models are implemented to capture all possible wave modes supported by the plate structure. A linear elastic constitutive law is adopted and the following mechanical parameters used for the plate material (aluminum): density $\rho = 2700$ kg/m$^3$, Young modulus $E = 70$ GPa, and Poisson ratio $\nu = 0.33$. The elastic domain is meshed by means of 8-node hexedral elements of maximum size $L_{FE} = 0.5$ mm, which is found to provide accurate eigensolutions up to the frequency of interest [39].

The band structures shown in Figs. 1(d)–1(f) are obtained assuming periodic conditions along the lattice vectors $a_1$ and $a_2$. Dispersion diagrams shown in Fig. 2 are computed instead considering a $20 \times 1$ $a_1$-periodic strip. The resulting eigenvalue problem $(K - \omega^2M)u = 0$ is solved by varying the nondimensional wave vector $k$ along the boundaries of the irreducible Brillouin zone $[\Gamma, M, K]$ for dispersion diagrams in Figs. 1(d)–1(f) and within $[-\pi, \pi]$ for band structures presented in Fig. 2.

The distribution of the von Mises stress fields reported in Figs. 3(c) and 3(d) are conducted in the frequency domain via the finite element solver ABAQUS. Free boundary conditions are applied at the edges of waveguide.

APPENDIX B: EXPERIMENTAL MEASUREMENTS AND DATA PROCESSING

The plate, consisting of 35 (in the $a_1$ direction) $\times$ 25 (in the $a_2$ direction) unit cells, is fabricated through a two-step machining process. First, the triangular holes are obtained through water-jet cutting. Circular blind and through holes are then obtained via a computer assisted drilling process. The specimen is made of aluminum 6082 T6, with the following nominal properties: density $\rho = 2700$ kg/m$^3$, Young modulus $E = 70$ GPa, and Poisson ratio $\nu = 0.33$. The plate dimensions and key geometrical parameters are as follows: $a = 20.5$ mm, $H = 5.9$ mm, $h = 0.5$ mm, $R = 1.75$, and $r = 0.8$ mm. Elastic waves are excited through a piezoelectric disk (12 mm diameter) bonded to the top surface of the plate at location shown in Fig. 3(b). Ultrasonic pulses consisting of 51 sine cycles modulated by a Hanning window of central frequency of 98 kHz are used as the excitation signals.

The experimental wave fields shown in Figs. 4(b) and 4(f) are recorded by a scanning laser Doppler vibrometer (SLDV) that measures the out-of-plane velocity of points belonging to a predefined grid over the structure. The spatial resolution of the grid is approximately 0.2 mm for the 2D local scan represented by the red dotted area in Fig. 3(b) and 0.6 mm for the 2D local scan in the blue dotted area also in Fig. 3(b).

The frequency/wavenumber representation of the edge modes presented in Fig. 4(a) are obtained by performing a temporal and spatial Fourier transform (2D-FT) of the signals detected along the 1D-scan lines reported as black dotted lines in Fig. 3(b). The wavenumber content of the 2D scan wave field shown in Figs. 4(f)–4(h) are obtained by performing spatial 2D-FT of the acquired data interpolated over a regular square grid. Filtering in the wavenumber domain [38] for modal separation relies on the application of 2D Gaussian windowing functions centered at wavenumber $k_1$, which can be expressed as follows:

$$H(k_1, k_2) = e^{-\frac{-k_1^2 + k_2^2}{2\sigma^2}},$$

where $i = 1, 2$, with $k_1 = 60$ rad/m, $k_2 = 80$ rad/m, $k = \sqrt{k_1^2 + k_2^2}$, $\sigma^2 = 50$. The wave fields corresponding to the separated modal contributions shown in Figs. 4(g) and 4(h) are obtained through an inverse 2D-FT of the filtered wavenumber representations shown in Figs. 4(d) and 4(e).

APPENDIX C: THE SPECIMEN MANUFACTURING AND FURTHER EXPERIMENTAL MEASUREMENT DETAILS

Figure 5 reports the digital models implemented in Auto-Cad for the computer aided design supporting the two-step machining process. A pristine aluminum plate of 6 $\pm$ 0.3 mm of thickness is grounded to a thickness of $H = 5.9$ mm and then waterjet machining according to the design reported in Fig. 5(a). Next, circular blind and through-the-thickness holes are drilled by means of a drilling machine according to the color scheme of Fig. 5(b): holes in red (green) define the $H^+$ ($H^-$) topological phase and are blind, i.e., drilled for a height of $h = 5.4$ mm from the top (bottom) to the bottom (top) of the plate with a radius $R = 1.75$ mm. Holes in blue (violet) define the $V^R$ ($V^\prime$) topological phase and are drilled through the plate thickness, with a radius of $R = 1.75$ ($r = 0.90$) mm.

Figure 6 reports the time history of the ultrasonic pulse fed to the piezoelectric transducer (12 mm of diameter and 1 mm of thickness) bonded to the top surface of the plate [yellow dot in Fig. 3(b)] and used to excite the elastic waves. It consists of 51 sine cycles modulated by a Hanning window of central
FIG. 5. Digital models assisting the two steps machining process. (a) Digital model assisting the waterjet cutting. (b) Digital model assisting the drilling machine. Holes in red (green) define the $H^+$ ($H^-$) topological phase and are blind, i.e., drilled for a height of $h = 5.4$ mm from the top (bottom) to the bottom (top) of the plate with a radius $R = 1.75$ mm. Holes in blue (violet) define the $V^R$ ($V^r$) topological phase and are drilled through the plate thickness, with a radius of $R = 1.75$ ($r = 0.90$) mm.

The scanning laser Doppler vibrometer (SLDV) acquiring the out-of-plane velocity is positioned perpendicularly to the plate, 102 cm away from the surface to monitor. The acquired signals are recorded using a sampling ratio of 40,000 points and multiple (64) measurements are performed and averaged for each acquisition point to increase the signal to noise ratio.

APPENDIX D: FURTHER INSIGHTS ON THE CONCEPT OF POSITIVE AND NEGATIVE SPIN FOR THE HV MODES

The two heterogeneous edge modes $\Psi^{+,-}$ supported by the $I(H^+, V^R)$ and $I(H^-, V^r)$ interfaces are characterized by opposite spin while propagating the energy (rightward or leftward). This can be seen as an opposite condition of vorticity of the wave while propagating. Specifically, Fig. 7 shows a schematics of the two conditions (for the rightward propagating case), where the vorticity of the velocity field of the unit cells composing the two topological phases defining the interfaces (straight black line) is reported as circular arrows: in the case of $I(H^+, V^R)$ interface, the positive spin reveals an anticlockwise (clockwise) vorticity of the velocity field for the $H^+$ ($V^R$) unit cell. The situation is reversed for the case of $I(H^-, V^r)$ interface.

APPENDIX E: NUMERICAL PROCEDURE AND ADDITIONAL NUMERICAL FULL MODEL SIMULATION

The dynamic response of the plate is governed by the elastic equilibrium equation for an isotropic material, which has the well known form

$$\rho \ddot{u} = (\lambda + \mu) \nabla (\nabla \cdot u) + \mu \nabla^2 u = 0,$$

where $\rho$ is the density of the material, $u$ denotes the displacement vector field, while $\lambda, \mu$ are the Lamé constants. The discretized form of this equation is employed within the COMSOL finite element environment, where full a 3D finite element model is developed in order to capture all possible wave modes. The existence of the modes predicted in Fig. 2 is also verified by additional transient numerical simulations of the full 3D finite element (FE) model formulated using ABAQUS as a solver. Calculations are conducted in the time domain, reproducing the same experimental configuration (both in terms of location and input signal exciting elastic waves). The transient animations are reported in the SM as movies showing the distribution of the von Mises stress field as a function of time. See Appendix F for further details on the animation of the numerical full wave field reconstruction.

APPENDIX F: WAVENUMBER FILTERING

In what follows, the steps to perform the 2D-FT and the wavenumber filtering procedure are discussed in detail. Figure 8 reports a schematic representation of the procedure which consists of five steps [38]:

1. The data are acquired in the direct domain by means of a SLDV over an irregular grid (black dots).
2. The data are interpolated over a regular grid of 121 points both in the $x$ and $y$ direction (red dots).
3. The data are transformed to the spatial domain by means of a 2D-FT.
4. The data are filtered by means of a band-pass filter.
5. The data are transformed back to the direct domain by means of an inverse 2D-FT.

FIG. 6. Excitation pulse. Temporal (upper panel) and frequency content (lower panel) of the applied pulse made of 98 kHz centered 51 sinusoidal cycles modulated by a Hanning window.
FIG. 7. Concepts of positive and negative spin for the HV modes. Schematics of the (a) $I(H^+, V^R)$ and (b) $I(H^-, V^r)$ interfaces (black line) along with the vorticity of the (rightward) propagating velocity field of the heterogeneous HV wave. In the case of $I(H^+, V^R)$ interface, the positive spin reveals an anticlockwise (clockwise) vorticity of the velocity field for the $H^+$ ($V^R$) unit cell. The situation is reversed for the case of $I(H^-, V^r)$ interface. The black circular arrows indicate the vorticity (clockwise or anticlockwise) expected above and below the interface and the straight arrow the rightward propagation.

FIG. 8. Wavenumber filtering. Schematic representation of the wavenumber filtering procedure.
(3) The interpolated data are 2D-FT in order to obtain their representation in the wavenumber domain ($x \rightarrow k_x$, $y \rightarrow k_y$).

(4) Applying ad-hoc designed filters it is possible to selectively filter specific wave components, offering the opportunity to further isolate the wavenumber components of the $\Psi^+$ and $\Psi^-$ modes.

(5) Inverse Fourier transforming the filtered data (in the wavenumber domain) allows us the reconstruct the wave field in the direct space for the single modes $\Psi^+$ or $\Psi^-$ (see Fig. 4) propagating along the $\mathcal{I}(H^+, V^R)$ and $\mathcal{I}(H^-, V^R)$ interfaces, respectively.
