(September 13, 2008)

We propose to monitor a qubit with a double-dot (DD) resonant-tunneling detector, which can operate at higher temperatures than a single-dot detector. In order to assess the effectiveness of this device, we derive rate equations for the density matrix of the entire system. We show that the signal-to-noise ratio can be greatly improved by a proper choice of the parameters and location of the detector. We demonstrate that quantum interference effects within the DD detector play an important role in the measurement. Surprisingly, these effects produce a systematic measurement error, even when the entire system is in a stationary state.

PACS: 73.50.-h, 73.23.-b, 03.65.Yz.

The single electron transistor (SET) is a sensitive device for quantum measurements [1–3]. It can be used as a monitor of a charge qubit, provided that the energy level $E_0$ carrying the current is close to the Fermi levels of the reservoirs $\mu_{L,R}$ [see Fig. 1(A,A')] or due to the electrostatic repulsion $U$ between the electrons, the SET current drops when the qubit is in the state $E_2$, as in Fig. 1(A')

FIG. 1: The qubit measurements using the SET detector (A,A') and the DD detector (B,B'). The detector current $I$ drops down whenever the state $E_2$ of the qubit is occupied. $\Gamma_{L,R}$ represent tunneling rates to the reservoirs and $\gamma$ denotes the interdot coupling.

Because of quantum interference effects, the dynamics of the measurement process using the DD detector is more complicated than with the SET detector. An electron flowing through the DD can be trapped in a linear superposition of the dot states. As a result, quantum interference could modify the signal in such a way that the DD cannot monitor the qubit. It is necessary to analyze the influence of the DD on the qubit motion (and vice versa) in order to establish the optimal conditions for utilizing the DD as an effective quantum detector. This can be done by solving the Schrödinger equation describing the combined system of qubit and detector.

In fact, the setup shown in Fig. 1(B,B') represents a generic class of non-demolition quantum measurements where a measured system interacts with only one state of the apparatus, while the apparatus may be in a superposition of states. This can take place in many devices based on interference, for instance in Electronic Mach-Zehnder Interferometer [8,9]. We therefore believe that our analysis of a qubit interacting with the DD detector can be useful for understanding many different quantum measurements.

Let us describe the entire setup shown in Fig. 1(B,B') by the tunneling Hamiltonian $H = H_q + H_{dd} + H_{int}$, where

$$H_q = E_1 a_1 a_1 + E_2 a_2 a_2 + \Omega (a_1^\dagger a_2 + a_2^\dagger a_1)$$

$$H_{dd} = H_0 + E_0 (c_1^\dagger c_1 + c_2^\dagger c_2) + \gamma (c_1^\dagger c_1 c_2 + c_2^\dagger c_2)$$

$$+ \sum_{\lambda} (\Omega_{\lambda}^L c_1^\dagger c_{\lambda}^R + \Omega_{\lambda}^R c_2^\dagger c_{\lambda}^L + H.c.) + \tilde{U}_{12} c_1^\dagger c_1 c_2^\dagger c_2$$

$$H_{int} = U a_1^\dagger a_2 c_1^\dagger c_2$$

are the qubit and the DD Hamiltonians, and $H_{int}$ is their interaction. Here $a^\dagger (a)$ is the creation (annihilation) operator for the electron in the qubit and $c^\dagger (c)$ is the same operator for the DD; $\Omega$ is the coupling between the states $|a_1^\dagger a_2^\dagger 0 \rangle$ of the qubit, and $\gamma$ is the coupling between the states $|c_1^\dagger c_2^\dagger 0 \rangle$ of the DD. The Hamiltonian $H_0 = \sum_{\lambda} [E_{\lambda}^L (c_{\lambda}^R)^\dagger c_{\lambda}^L + E_{\lambda}^R (c_{\lambda}^L)^\dagger c_{\lambda}^R]$ describes the reservoirs, where $\Omega_{\lambda}^L$ are the couplings between the right and left dots with the right and left reservoirs. We assume weak energy dependence of these couplings, $\Omega_{\lambda}^L \approx \Omega_{L,R}$. Then the corresponding tunneling rates are $\Gamma_{L,R} = 2\pi \rho_{L,R} \Omega_{L,R}^2$, where $\rho_{L,R}$ are the density of
states in the reservoirs. The latter quantities are also weakly dependent of energy. The last term in $H_{dd}$ describes the inter-dot repulsion. For simplicity we consider electrons as spinless fermions.

Using the technique developed in Ref. [10,11] for the case of large bias voltage, $V = \mu_L - \mu_R$, we can partially trace out the reservoir states in the equation of motion for the density matrix of an entire system, $i\dot{\rho} = [H, \rho]$. As a result we arrive at the Bloch-type rate equations for the reduced density-matrix, $\sigma^{ij}_n(t)$, describing the qubit-detector evolution, where the indices $i, j$ denote all available discrete states of the detector-qubit system and $n$ denotes the number of electrons which have arrived at the right reservoir by time $t$. In our case, Fig. (1B,B'), the available discrete states are labeled (a, b, c, d), denoting the cases that the DD is empty (a), the left dot of the DD system is occupied (b), the right dot of the DD system is occupied (c), and both dots are occupied (d), while the electron of the qubit occupies the level $E_1$ (see Fig. 1B). Correspondingly, $(a', b', c', d')$ denote the same states but where the electron of the qubit occupies the level $E_2$ (see Fig. 1B'). If the inter-dot repulsion is large, $\tilde{U}_{12} \gg V$, the states $d', d''$ do not contribute terms to the equations of motion. We obtain in this case [10-12]:

\[
\begin{align*}
\dot{\rho}_{aa} &= -\Gamma_L\rho_{aa} + \Gamma_R\rho_{cc} + i\Omega(\rho_{a'a'} - \rho_{aa}) \\
\dot{\rho}_{ab} &= \Gamma_L\rho_{aa} + i\Omega(\rho_{b'a'} - \rho_{bb}) + i\gamma(\rho_{b'b'} - \rho_{bb}) \\
\dot{\rho}_{bb} &= \Gamma_L\rho_{bb} + i\Omega(\rho_{b'b'} - \rho_{bb}) + i\gamma(\rho_{b'b'} - \rho_{bb}) \\
\dot{\rho}_{bc} &= -\Gamma_L\rho_{bc} + i\Omega(\rho_{b'b'} - \rho_{cc}) + i\gamma(\rho_{b'b'} - \rho_{cc}) \\
\dot{\rho}_{cc} &= -\Gamma_L\rho_{cc} + i\Omega(\rho_{c'c'} - \rho_{cc}) + i\gamma(\rho_{c'c'} - \rho_{cc}) \\
\dot{\rho}_{c'd'} &= \Gamma_L\rho_{c'd'} + i\Omega(\rho_{c'c'} - \rho_{dd}) + i\gamma(\rho_{c'c'} - \rho_{dd}) \\
\dot{\rho}_{d'} &= i\Omega(\rho_{d'd'} - \rho_{dd}) + i\gamma(\rho_{d'd'} - \rho_{dd}) - \frac{\Gamma_R}{2}\rho_{d'd'} \\
\dot{\rho}_{c'd'} &= iU\rho_{c'd'} + i\Omega(\rho_{c'c'} - \rho_{cc}) + i\gamma(\rho_{c'c'} - \rho_{cc}) - \frac{\Gamma_R}{2}\rho_{c'd'} \\
\dot{\rho}_{dd'} &= i\Omega(\rho_{dd'} - \rho_{dd}) + i\gamma(\rho_{dd'} - \rho_{dd}) - \frac{\Gamma_R}{2}\rho_{dd'}
\end{align*}
\]

Note that these equations are obtained from the original many-body equations $i\dot{\rho} = [H, \rho]$ without the explicit use of any Markov-type or weak-coupling approximations in the case of large bias voltage, $V \gg \Gamma_{L,R}, U$ [10,11]. There are no other limitation on $U$, in contrast with our analysis of the SET detector [12].

Equations (2) are different from the standard master equations, describing quantum system interacting with the environment (detector) by keeping track of the environment variables. In our case this is the number of electrons ($n$) arriving the collector. This allows us to find the time evolution of the qubit and the detector at once. For instance, the qubit behavior is described by the (reduced) density matrix $\sigma_{ij}(t) = \{\sigma_{\alpha\beta}(t)\}$ with $\alpha, \beta = \{1, 2\}$, where $\sigma_{11} = \sum_n(\rho_{aa}^n + \rho_{bb}^n + \rho_{cc}^n)$, $\sigma_{12} = \sum_n(\rho_{aa}^n + \rho_{bb}^n + \rho_{cc}^n)$ and $\sigma_{22} = 1 - \sigma_{11}$.

On the other hand, by tracing out the qubit variables we obtain the probability of finding $n$ electrons which have arrived at the collector, $P_n(t) = \sum\sigma_{jj}^n(t)$. This quantity allows us to determine the average detector current and its shot-noise spectrum. The former is given by

\[
I(t) = e\sum_n n\dot{P}_n = e\Gamma_R\sigma_{R}(t),
\]

where $\sigma_{R}(t) = \sum n[\rho_{cc}^n(t) + \rho_{dd}^n(t)]$ is the probability that the right dot is occupied. The shot-noise spectrum, $S(\omega)$, is obtained from the McDonald formula [13,14]

\[
S(\omega) = 2e^2\omega \int_0^\infty dt \sin(\omega t) \sum_n n^2\dot{P}_n(t),
\]

One finds from Eqs. (2), (4) that

\[
S(\omega) = 2e^2\omega \Gamma_R \text{Im} [Z_{cc}(\omega) + Z_{dc}^*(\omega)],
\]

where $Z_{ij}(\omega) = \int_0^\infty \sum_n (2n + 1)\rho_{ij}^n(\omega) \exp(\omega t)dt$. These quantities are obtained directly from Eqs. (2) which are reduced to a system of linear algebraic equations after the corresponding integration over $t$ [15].

Consider first the static qubit, $\Omega = 0$. Solving Eqs. (2) for this case one finds that the stationary current, $I = I(t \to \infty)$, is obtained by the value $I_1 = \Gamma_R\sigma_R(U = 0)$ when the qubit is in the state $E_1$, and $I_2 = \Gamma_R\sigma_R(U)$ when the qubit is in the state $E_2$, Fig. 1(B,B'), where

\[
\bar{\sigma}_R(U) = \frac{\gamma^2}{U^2 + \frac{\gamma^2}{4} + \gamma^2(2 + \frac{\gamma^2}{4})}.
\]

As expected, the detector current decreases whenever the electron of the qubit is close to the DD detector. Consider now $\Omega \neq 0$. We assume that for an “ideal” detector its average current would follow the qubit motion [16],

\[
I(t) = I_1\sigma_{11}(t) + I_2[1 - \sigma_{11}(t)].
\]

This condition, however, cannot be fully met since the detector’s response is limited by the rate of tunneling from the right dot to the collector. Nevertheless, if this transition is fast enough compared to the qubit frequency, $\Gamma_R \gg \Omega$, one expects to approach Eq. (7).

Let us compare $\sigma_{11}(t)$ with the average “signal,” $\langle I(t) - I_2(K)\rangle/\Delta I$, where $\Delta I = I_1 - I_2$. The results of our calculations for $\gamma = \Omega$ are presented in Fig. 2. The initial conditions correspond to the qubit electron in the upper
dot and the detector current $I(t = 0) = \bar{I}_1$. One finds that the detector does not follow the qubit oscillations well when $\Gamma_R = \gamma$, Fig. 2(a). On the other hand, in Fig. 2(b) where $\Gamma_R \gg \gamma$, the detector performance is much improved, in accordance with our arguments.

![Fig. 2: The probability of finding the qubit in the state $E_1$, (dashed line) compared with the average detector signal, $|I(t) - \bar{I}_2|/\Delta I$ (solid line) as a function of time for $\gamma = \Omega$ and $U = 5\Omega$, $\Gamma_L = 5\Omega$.](image)

The results displayed in Fig. 2(a) are surprising. One expects that in the steady-state limit ($t \to \infty$) the average detector current should be distributed between the values $I_1$ and $I_2$, with probabilities $\sigma_{11}$ and $1 - \sigma_{11}$ to find the qubit in the states $E_{1,2}$, respectively. Equation (7) should thus always hold in the limit of $t \to \infty$ for any such device (for instance, the SET detector [12]). In the case of the DD detector, however, Eq. (7) does not hold in the steady-state limit, as seen in Fig. 2(a). In fact, this can be obtained analytically in the limit of small $U$ by expanding the stationary current, $\bar{I} = I(t \to \infty)$, Eq. (3), in powers of $U$. One finds for the detector’s signal:

$$\frac{\bar{I} - \bar{I}_2}{\Delta I} = \left[1 + \frac{2}{4 + (\Gamma_R/2\Omega)^2} + O(U^2)\right] \sigma_{11}(t \to \infty)$$  \hspace{1cm} (8)

It follows from this expression that a mismatch between the signal and the qubit ($\sigma_{11}$) survive even in the limit $U \to 0$. In this case it depends only on the ratio $\Gamma_R/\Omega$. The other detector parameters $\gamma$ and $\Gamma_L$ enter only in the term proportional to $U^2$.

So where is the “hidden” probability that is responsible for the systematic error in the qubit measurements? It can be recovered in the linear superposition of the detector and qubit states. The DD current flows via two discrete energy levels, $E_0$ and $E_0 + U$. A carrier wave function thus proceeds through a linear superposition of these states, $b(b')$ and $c(c')$. The qubit is itself a two level system described by superposition. These different superpositions involve the same states $(b, b', c, c')$ of the entire system, and hence are entangled. This is reflected in the off-diagonal terms $\sigma_{bc}$ and $\sigma_{bc'}$, Eqs. (2). As a result the superposition of qubit states (qubit’s “phase”) directly affects the DD dynamics, leading to a violation of Eq. (7). This would happen even in the limit $U \to \infty$. In this case the state $(c')$ disappears from Eqs. (2), but the off-diagonal term $\sigma_{cb'}$ would still survive in the limit $t \to \infty$. One should note that in the case of the SET such entanglement cannot occur. Therefore Eq. (7) holds for the SET, even though $\sigma_{12}(t \to \infty) \neq 0$.

We find from Fig. 2 and Eq. (7) that the detector’s performance improves when $\Gamma_R \gg \Omega$. At the same time, however, its average signal decreases. In order to assess the detector’s efficiency this signal should be compared with its noise. An appropriate measure of the detector efficiency is the integrated signal to noise ratio [19,2], $s/n = \int_{-\infty}^{\infty} |I_{sig}(\omega)|^2/S(\omega)d\omega/2\pi$. The signal $I_{sig}(\omega) = \int_{0}^{\infty} [I(t) - I(t \to \infty)] \exp(i\omega t)dt$ corresponds to a deviation of the detector current from its stationary value, and can be evaluated using Eqs. (2), (3), and (5).

We show in Fig. 3 how the integrated signal to noise ratio behaves as a function of both $U$ and the ratio $\Gamma_R/\gamma$, for $\Gamma_L = 5\Omega$ and $\gamma = \Omega$. A peak is observed uniformly throughout the range of $U$ at $\gamma \approx 0.4\Gamma_R$. The signal to noise ratio depends weakly on $U$ when $U/\Omega \gtrsim 15$, allowing good operation even at low values of $U$. Comparing the performances of the DD and the SET detectors, we see that the maximal signal to noise ratios obtained are comparable. However, the SET reaches these values only in the asymmetric limit $\Gamma_R \gg \Gamma_L$ [12], while the DD detector’s signal to noise ratio is shown to be optimized without such a restriction.

![Fig. 3: The integrated signal to noise ratio of the DD detector. Here $\gamma = \Omega, \Gamma_L = 5\Omega$.](image)

The results so far presented refer to a qubit that is positioned near the right dot of the detector. One may ask what happens when the qubit is positioned near the left dot. It was suggested in Refs. [20,12] that the performance of any quantum detector would improve if the detector were to operate mostly in the states where there
is no actual interaction with the qubit. By this argument one can expect that putting the qubit near the left dot would lead to poor performance. Indeed, in this case the misalignment of the energy levels prevents electron propagation to the right dot, so that the electron is pinned to the left dot. This increases the weight of states where the detector interacts with the qubit. On the other hand, if the qubit is located near the right dot as in Fig. 1(B,B’), the same misalignment of levels localizes the electron in the left dot, diminishing the occupation of the right dot, Eq. (6). As a result, the actual interaction with the detector decreases and so it is expected to operate better.

Our conclusion about the asymmetry with respect to the qubit’s location can be confirmed by direct evaluation of the detector efficiency, in the same way as presented in Figs. 2 and 3. We can also confirm it in a different way by evaluating the power spectrum of the detector current, $S(\omega)$, via Eq. (5). This displays a pronounced peak at $\omega = 2\Omega$, generated by the qubit oscillations. It was argued in Ref. [18] that the peak-to-background ratio, $S(2\Omega)/S(\omega \rightarrow \infty)$, is a measure of the detector efficiency. Figure 4 exhibits this ratio for the two qubit positions as a function of $U$. As we increase the misalignment of the levels we find that the two curves separate. Thus, the setup with the qubit near the right dot is indeed more effective, in accordance with our arguments. Note that the peak-to-background ratio for this setup depends weakly on $U$ for $U/\Omega \gtrsim 15$. We have already noted that the signal-to-noise ratio, which is another criterion of the detector efficiency, shows a similar behavior.

![Fig. 4: The peak to background ratio of the current power spectrum as a function $U$ for $\Gamma_{L} = 5\Omega$, $\Gamma_{R} = 10\Omega$ and $\gamma = \Omega$. Solid line: qubit positioned next to the detector’s left dot, dotted: qubit positioned next to the detector’s right dot.](image)

We can show that the maximal value of the peak-to-background ratio for the DD detector approaches 3 when $\Gamma_{R}, U \gg \gamma, \Omega$ (the dependence on $\Gamma_{L}$ is not essential). The same maximal value was obtained for the SET detector [12]. Therefore, while both detectors are sensitive measurement devices, they do not reach the effectiveness of an ideal detector [18].

In summary, we have proposed the use of a double dot structure for the measurement of a charge qubit. We obtained a set of rate equations describing the entire system and displayed the conditions under which such a measurement is effective. We found the measurement to be most sensitive when the detector operates mainly in the states where no interaction with the qubit takes place. We further demonstrated that, because of quantum interference effects inside the detector, the stationary current is not determined solely by the probabilities of the stationary qubit, but reflects the qubit phase as well.
