Editorial

The evaluation of corneal pachymetry has acquired importance in recent years, especially in the preoperative screening of refractive surgery cases. In addition to corneal thickness, studying the distribution of corneal epithelial thickness is becoming a very useful parameter, both clinically and in research settings. Evaluation of the corneal epithelial map can help clinicians in everyday decision-making and to a safer screening for refractive surgery candidates. Topographic irregularities of epithelial pachymetry either localized or diffuse, can significantly affect the overall corneal refractive power. In addition, corneal epithelium in several cases may be masking underlying stromal disorders.

Examination tools for studying epithelial thickness comprise several imaging devices such as scanning high frequency ultrasound (HF-UBM, Artemis), confocal microscopy and anterior segment optical coherence tomography (AS-OCT). The latter provides optical corneal sections and simultaneously pachymetric data through interpolation of successive radially oriented B-scans. The most advanced AS-OCTs currently use spectral-domain Fourier analysis (SD-OCT), providing significantly higher speed and better resolution compared to earlier, time-domain tomographers (TD-OCT). The additional feature of an AS-OCT system is the 3D imaging of the corneal epithelium. This provides a practical clinical tool for mapping corneal epithelium in vivo, with the advantage of intact, rapid data acquisition. In our center, we use both the RTVue-100 and the Avanti systems (Optovue) as valuable tools for our everyday clinical practice as well as for our clinical research purposes. Our team has published extensive studies on the behavior of the epithelium in a variety of ophthalmic conditions.

The following is a summary of our current knowledge:

The corneal epithelium in normal eyes: The distribution of epithelial maps has been studied in 373 normal subjects. Epithelial pachymetry shows a nearly normal distribution with a mean thickness of 53.28±3.34 microns (range 45-60 μm), while the topographical variation (variability) is 1.78±0.78 microns. The corneal epithelium was also found to be slightly thicker in the lower half of the cornea. A positive correlation between age and epithelial pachymetric abnormality was also observed (increase abnormality of the epithelium with age) [1].

The corneal epithelium in ectasia and keratoconus: It is known from earlier studies with the HF-UBM Artemis system that the corneal epithelium has a compensation function, trying to “cover” topographic anomalies of the underlying stromal layers. The epithelium, for example, becomes thinner over the cone in keratoconic eyes, and correspondingly thicker in the flattest area. This was also identified in our study with AC-OCT [2]. We have further shown that in keratoconic eyes there is an overall increase in the average corneal epithelial thickness, particularly in younger patients [3]. Indeed, in our opinion, this “reactive” epithelial hypertrophy can be a very early diagnostic marker of subclinical keratoconus before any other topographic (Placido) or tomographic (Scheimpflug) sign becomes evident.

Furthermore, we have shown that the corneal epithelium asymmetry indices and the area of local thinning, both provided by the OCT exam, correlate very well with the anterior corneal keratoconus indices (such as the ISV and IHD indices) provided by Scheimplug technology [4]. It is of particular interest our finding that “normalization” of the epithelial topography occurs after a combined excimer laser (customized PRK) and corneal cross-link procedure in keratoconus patients (Athens Protocol). Detailed 12-month postoperative monitoring of keratoconic eyes who underwent Athens protocol, showed an overall thinning and normalization of the epithelial profile (approaching absolutely normal values) compared to untreated keratoconic eyes [5] (example in Figure 1).

The corneal epithelium in dry eye: We have observed an overall increase in epithelial thickness in dry eyes (average 58 μm). The topographic variance is comparable to the normal eye (mean of 3 μm). These findings are likely to play a key role in the preoperative and postoperative assessment of refractive patients and in some cases may precede the appearance of other specific dry eye-tests such as TBUIT and Schirmer’s [6].

The corneal epithelium following cataract surgery: We have analyzed corneal epithelium with AS-OCT, preoperatively and 3 months postoperatively, in 116 eyes undergoing cataract surgery. Due to epithelial remodeling occurring after cataract surgery, the epithelium returns to preoperative values at the third postoperative month. Delayed remodeling was seen in elderly (age>75 years) patients [7].
The corneal epithelium after LASIK: Changes in the thickness of the corneal epithelium following myopic LASIK correction with mechanical microkeratome have been reported in previous studies. The increase in the central epithelium thickness observed after LASIK, was attributed to refractive regression. In our own studies we have seen only a mild increase (average 3 μm) of the epithelium thickness, which was rather non-lenticular, and more evident in the middle corneal region, at 5 mm diameter area. Moreover, a positive correlation with the amount of attempted correction was found; the higher the attempted myopic correction and therefore the flattening of the cornea, the greater the increase in epithelial thickness [8]. Comparison of the postoperative epithelium between patients undertaking ‘standard’ LASIK vs. LASIK with simultaneous prophylactic corneal crosslink (Lasik-Xtra), revealed that when cornea cross-linking is applied, no corresponding increase in the epithelial thickness is observed [9]. The differences found, cannot be fully explained according to the theory of epithelial compensation response. One explanation which we propose might be the reduced epithelial hyperactivity as a result of increased structural bio-tectonics (rigidity) of corneas following cross linking. This may not allow large oscillations in the cornea.

Certainly, much remains to be studied and explained in relation to the behavior of the epithelium in various corneal pathologies. However, technological advancements such as the AC-OCT, provide us with the ability of in vivo detailed information.
