We theoretically study the non-linear response of interacting neutral bosonic gas in a synthetically driven one-dimensional optical lattice. In particular, we examine the bosonic analogue of electronic higher harmonic generation in a strong time-dependent synthetic vector potential manifesting itself as the synthetic electric field. We show that the vector potential can generate reasonably high harmonics in the insulating regime, while the superfluid regime exhibits only a few harmonics. In the insulating regime, the number of harmonics increases with the increase in the strength of the vector potential. This originates primarily due to the field-driven resonant and non-resonant excitations in the neutral Mott state and their recombination with the ground state. If the repulsive interaction between two atoms ($U$) is close to the strength of the gauge potential ($A_0$), the resonant quasiparticle-quasihole pairs on nearest-neighbor sites, namely dipole states are found to play a dominant role in the generating higher harmonics. However, in the strong-field limit $A_0 \gg U$, the nonresonant states where quasiparticle-quasihole pairs are not on nearest-neighbor sites give rise to higher harmonics.

I. INTRODUCTION

The interplay between intense laser field and matter continues to be a field of extensive research both theoretically and experimentally as it allows to decode microscopic mechanism of several physical systems such as photonic, gaseous, solid-state and quantum spin systems. The non-perturbative nature of the matter-light interaction makes the field even more promising due to its potential for exhibiting unprecedented and rich physics. For example, the generation of higher harmonics in gaseous systems,9–9, leading to plateaus in the energy distribution of emitted light, has stimulated research for several decades and has now become a key candidate for attosecond science. Recently, the higher harmonic generation (HHG) has been experimentally observed and theoretically studied in solid-state systems and semimetals. While gas phase HHG is limited to complex experimental set-ups and millijoule class laser pump, the solid-state HHG turns out to be easily achievable and non-destructive. Thus it emerges as a potential platform for ultrafast and short wavelength coherent light sources. A great volume of work suggested that the HHG in solid-state system can be used to probe the electronic properties of a wide range of materials. It has been also shown that engineered solid-state structure can be used as a possible candidate for producing stable extreme ultraviolet (XUV) waveforms.

While most of the studies on HHG in gas and solid-state systems either assume weak interaction or those are based on single particle picture, only a few recent studies have addressed HHG in strongly correlated electronic systems such as Mott insulators. Using fermionic Hubbard model, it has been shown that the HHG can be used to resolve ultrafast many-body dynamics in a Mott insulator. In the strong-field, the mechanism that leads to HHG in Mott insulators turns out to be a recombination of field-excited doublon-holon pairs with the ground states. In contrast, in the low-field limit, the itinerant doublon-holon excitations play the role in generating higher harmonics. Given HHG in interacting fermionic Mott insulators, it is natural to ask if analogous higher harmonics can also be obtained in a bosonic Mott insulator of interacting neutral bosons loaded in optical lattice under a synthetic electric field. If yes, what is the underlying mechanism for the generation of such higher harmonics in the bosonic Mott insulators? Since the typical notion of doublon-holon excitations in fermionic Mott insulators cannot be extended to bosonic systems, this poses a pertinent question that needs to be addressed. Bosons in optical lattices are known to exhibit a class of excitations depending on the strength of the applied electric field. It is also thus important to discern how various types of excitations contribute to HHG?

To address the above questions, we consider one-dimensional Bose-Hubbard model and theoretically study the
bosonic analogue of electronic HHG in different regimes of atom-atom interactions giving rise to the superfluid and Mott phases. We find that the dynamics of atoms in the superfluid regime is transparent to the synthetic vector potential. In contrast, the Mott insulating phase exhibits strikingly different optical responses. By varying the strength of the potential, we find the optical transitions involve an increasing order of harmonics in the Mott insulating regime. The superfluid regime remains unaffected as we increase the strength of the synthetic gauge potential. We show that the generation of higher harmonics in the Mott insulating regime can be attributed to the formation of resonant dipole states-a pair of quasiparticle and keyhole on nearest neighbor sites when the potential strength is comparable with the interaction $U$. On the contrary, in the strong field limit, the HHG is attributed to the non-resonant states where quasiparticle-quasihole pair resides on different sites.

Concerning experimental adaptability, the first challenge is to achieve a perfect Mott insulator at finite temperature in the context of the present theoretical study. However, it has been overcome by reducing the thermal entropy of the atoms in a novel and efficient way recently as outlined in Ref. 34. leading towards the realization of a strongly correlated Mott insulating state which is essential for creating HHG. The particle-hole excitations which are essential for HHG, as discussed in this work, can be created either by the synthetic vector potential in the presence of additional Raman lasers, or tilting the lattice with an additional gradient field\(^35\). Then the subsequent dynamics is expected to be measured in the time-of-flight experiments as illustrated in Refs. 36 and 37. We note that recently the response of the interacting ultracold atomic rubidium sample due to the application of the femtosecond laser pulse through the resonant and non-resonant channels has been experimentally studied in Ref. 38. Although this cold atom set-up is driven by electrons rather than bosons themselves, the identification of the specific channels forms the basis of our understanding behind the production of HHG as will be elucidated in the manuscript.

The rest of the paper is organized as follows. In Sec. II, we discuss the model and formalism in the presence of a synthetic electric field. In particular, we discuss the one-dimensional Bose-Hubbard model in the presence of a 10-cycle \(\sin^2\) pulse followed by a discussion on the numerical methods and coupling of the electric field with the neutral atoms. This is followed by Sec. III, where we present HHG spectrum for both Mott and superfluid regimes for different strength of the gauge potential, and explain the possible reason for such HHG. We furthermore show the evolution of fidelity for different atom-atom interaction. Finally, we conclude with a discussion on the possible future directions and experimental implications in Sec. IV.

II. MODEL AND METHODS

A. Bose-Hubbard Hamiltonian

We start with a gas of bosonic atoms at zero temperature trapped in an one-dimensional (1D) optical lattice potential. The statics and dynamics of this bosonic system can well be described by the single (lowest) band Bose-Hubbard (BH) Hamiltonian to emulate real condensed matter systems

\[
\hat{H} = -\sum_{\langle ll'\rangle} J \hat{a}_{l}^\dagger \hat{a}_{l'} + \frac{U}{2} \sum_{l} \hat{n}_{l}(\hat{n}_{l} - 1) - \mu \sum_{l} \hat{n}_{l}, \tag{1}
\]

where \(\langle ll'\rangle\) refers to nearest-neighbors (NN) \(l\) and \(l'\), \(J\) is the hopping strength between two NN sites, \(U\) is the interaction, \(\mu\) is the chemical potential, which sets the particle number \(N\) in the system, \(\hat{a}_{l}^\dagger(\hat{a}_{l})\) are the bosonic creation (annihilation) operators with \(\hat{n}_{l} = \hat{a}_{l}^\dagger \hat{a}_{l}\) as the occupation number in the \(l\)th lattice site. The model assumes that any excitation associated with the interaction \(U\) is smaller than the separation energy to the first excited band of the deep optical lattice\(^39,40\). Depending on the relative values of \(U/J\), this model supports two distinct phases. For \(U/J \gg 1\), the system exhibits gapped insulating phase, namely Mott-insulator (MI) with commensurate integer fillings and vanishing order parameter. The Mott gap is determined by the energy difference between a single particle excitation band (energy involving adding an extra particle in the Mott phase) and a single hole excitation band (energy involving removing a particle in the
Mott phase). Note that these particle-hole excitation bands are the genesis of higher harmonic orders as will be evident shortly. In contrast, $U/J \ll 1$ leads to the gapless superfluid (SF) phase with non-vanishing compressibility.\textsuperscript{35,39,41,42} Specifically, the presence of two gapless particle-hole excitation energy bands at $k = 0$ among the four constitutes the relevant superfluid physics.\textsuperscript{43} For the present work, we consider the average particle number per site to be 1 in the Mott phase.

### B. Synthetic electric field

As opposed to the HHG in gases and solid materials where electric field, $E(t)$ naturally couples to the electrons via time-varying vector potential, $A(t)$, the analogous HHG in bosonic neutral atoms arises due to coupling between the $A(t)$ and neutral atoms in a synthetic manner. Specifically, $A(t)$ can be regulated in an experiment by detuning of two Raman lasers which affect the mechanical momentum of the particles. In particular, the multiple internal states of the neutral atom are coupled with a slight off-resonant Raman lasers which in turn lead to dressed atoms. These dressed atoms behave like charged particles with an effective charge $q^*$ and they move with a finite velocity.\textsuperscript{36} This forms the basis of coupling between the neutral atoms and synthetic vector potential. Note that so far the experiments have demonstrated mostly static fields. However, the gauge fields can have externally imposed time dependence giving rise to effective time-dependent electric fields. This can be brought about periodically changing the external magnetic field, which in turn induces time dependence on the Zeeman shift of the atomic spin states. This would change the detuning periodically. There have been several proposals in generating dynamical gauge fields with ultracold atoms, however, owing to experimental limitations has hindered its progress.\textsuperscript{36,44} Considering this experimental fact and for the sake of studying HHG, we use a $n$-cycle $\sin^2$ time varying vector potential of the form of a pulse, $A(t) = A_0 \sin^2(\omega t/2n) \sin(\omega t)$ with $\omega$ being the frequency of oscillation, where $E(t) = -\partial_t A(t)$. The strength of the vector potential $A_0 \sin^2(\omega t/2n)$ smoothly varies with $t$ and the maximum value is attained at the half-cycle of the pulse. The $A(t)$ minimally couples to the system via the hopping term as $J e^{i\Phi(t)}$, where $\Phi(t) = q^* A(t) a$, with $a$ as the lattice constant. Figure 1 illustrates the schematic of light-atom coupling in 1D optical lattice set-up, which is synthetic in nature.

We point out that the variation of $A(t)$ which leads to the change in momentum with time, in turn, imparts a force on the dressed atoms and constitutes the effective particle current as discussed in Sec. III A. It could be also interpreted as radiation of a neutral system. Also, we note that the $A(t)$ can couple the particle-hole excitations giving rise to various resonant and nonresonant excitations (located within the gap between the lowest and first excited states) depending upon the ratio between $U$ and $A_0$, where $A_0$ is taken in units of energy.\textsuperscript{31} This will be discussed in Sec. III B.

### C. Numerical methods

To study the dynamics, we solve the time-dependent Schrödinger equation $\hat{H}(t) \psi(t) = i\hbar \frac{\partial \psi(t)}{\partial t}$ numerically. The ground state of the interacting Hamiltonian (Eq. 1) at $t = 0$ is computed for a lattice site of length $L = 7$ and total number of atoms $N = 7$, using exact diagonalization. It is then evolved under time-dependent Hamiltonian $H(t)$ using the Runge-Kutta algorithm choosing an optimum temporal step size which renders the dynamics convergent (see Appendix A). For a detailed review on the use of numerical methods to study HHG, the readers may refer to Ref. 45. With the evolved wavefunction, various quantities are computed to investigate the response of the interacting many-body system to the synthetic pulse. It may be mentioned here that with the increase in the system size, the dimension of the Hilbert space increases exponentially, and thus computing the dynamics becomes computationally expensive. We have thus refrained here from providing results for large system sizes, although, we have checked that the mechanism for HHG generation remains unchanged with the increase in the system size which is discussed in Appendix B.

### III. RESULTS AND DISCUSSIONS

#### A. HHG spectrum

To investigate the effect of light field, we first evaluate current operator defined as

$$J(t) = -i a q^* J \sum_{i=1}^{L} \left( e^{-i\Phi(t)} b_i^\dagger b_j - H.c. \right). \quad (2)$$

The HHG spectrum is obtained from the dipole acceleration $F(t) = dJ/dt$ in frequency space. Note that the non-linear current generated due to synthetic driving in this present study does not emit photons, in contrast to the real materials. Figure 2 shows HHG spectra in deep Mott insulating, intermediate and deep superfluid regimes for different strength of the gauge potential $A_0$. Evidently, there is a single dominant peak in the superfluid regime and the location of the peak does not change with the change in the strength of the potential. This is attributed to the lowest quasienergy band current without any higher quasienergy curve crossings, and is usually typical of any single band Hamiltonian under periodic driving.\textsuperscript{11} As mentioned before, since the superfluid phase is gapless, there is only one band and the application of synthetic electric field leads to typical Bloch-type oscillation within this band. In contrast, the Mott insulating phase, which is characterized by a gapped excitation spectrum, exhibits optical transitions between the quasienergy levels brought about by the coupling of particle-hole excitations. This is further associated with higher harmonics of the synthetic driving frequency. When $U/J = 5$, that is, in the intermediate regime, higher harmonics are also generated with the application of the synthetic light pulse as evident from Fig. 2b. However, the value of the
highest order harmonic for any \( A_0/J \) is less than what is obtained in the deep insulating regime. Furthermore, it is to be noted here that unlike the fermionic system studied in Ref. 28, as we increase the synthetic field strength \( A_0 \), the order of harmonics increases monotonically. The cutoff scaling law with the strength of the vector potential \( A_0 \) turns out to be linear as shown in Fig. 3, corroborating the typical scaling obtained in gases and solids.

For low order harmonics, the peaks appear exactly at odd-integer multiple, however, they deviate slightly for high order harmonics. As we increase the strength of the gauge field, the deviation starts to increase. This may be attributed to the unitary dynamics of the model that we consider. The absence of the bath induced dephasing terms in the current Hamiltonian leads to the offset of the odd harmonic spectrum for the higher orders \( 28,46,47 \). Cold atoms in optical potentials provide extremely clean conditions and do not suffer from dissipation induced by the coupling to phonons. However, dissipation can be introduced to get clear HHG peaks through non-Hermitian Hamiltonian, which is beyond the scope of our present study. Furthermore, in some cases, the prominent splitting of the peaks may be attributed to the current due to the coupled quasi-energy levels similar to the two-bands Bloch oscillation in a static field, where the dynamics of the two-band systems is characterized by two timescales as explained in Ref. 48.

The reason for the HHG in the bosonic system may be associated with the recombination of resonant and non-resonant excitations with the ground state in the presence of synthetic vector potential. These excitations do not have analogues to the real-systems, and the mechanism of HHG in real solids and gases is different. It is worth pointing out here that the energy scales for our current set-up should not be strictly compared to that of real solid-state systems or gases. Whether be it cold-atom or real materials, since the related physics should be scale-independent, we use normalized dimensionless units in all the relevant plots and discuss the mechanism. Thus, to understand the role of these excitations in HHG in cold atom setup, we first briefly review typical excitations in the Mott phase of an optical lattice in the presence of a static electric field.

### B. Excitations in the Mott insulating phase

A static electric field \( E \) introduces the Stark term \( H' = E \sum_i \hat{a}_i^\dagger \hat{a}_i \) in Eq. (1), which is equivalent to tilt or a linear potential gradient in the optical lattice in the coordinate space. We also note that the addition of \( H' \) is the same as modifying hopping \( J \) by Peierls phase involving electric field as discussed before. They are related by a simple gauge transformation as shown in Ref. 49. It is convenient to understand the excitation spectrum of the system and subsequent tunneling between the sites in terms of tilting of the optical lattice. In the Mott limit, i. e., \( J \ll U \), the typical “quasiparticle” and “quasihole” excitations can be created by adding a single particle on a site or removing one particle from a site (see Fig. (4)), respectively. Such quasiparticle or quasihole states over the Mott states turn out to be localized even in the presence of any finite gauge potential. Consequently, these states do not extend across the whole system to produce significant changes in the initial state. Thus such excitations of deformed Mott state with net finite charge cannot take part in generating higher harmonics. On the other hand, Mott state with zero net charge, usually called neutral Mott state produces various families of excitations in the presence of a synthetic electric field. The excitations of such Mott state are possible only if \( E \sim U \), where \( E \) is measured in units of energy. In this limit, a quasiparticle-quasihole pair is formed on nearest-neighbor sites and they may tunnel resonantly into the nearest site. These states are called dipole states and differ in energy from the Mott state by \( \sim E - U \) when \( J = 0 \). Thus at \( U = E \), states become degenerate and an infinitesimal \( J \) leads to a resonant coupling between them. In addition

---

**FIG. 3.** (Color online) Dependence of the high-order harmonic spectrum on the strength of the gauge potential for \( U/J = 10 \) revealing a linear cutoff law.

**FIG. 4.** (Color online) Schematic representation of deformed Mott insulators in a field-driven tilted optical lattice. a) a quasiparticle state at site 2, b) a quasihole state at site 2, c) a resonant state with a pair of quasiparticle-quasihole states on nearest-neighbor sites. This state is usually called dipole state, and d) A non-resonant states with a quasiparticle-quasihole pair are not on nearest-neighbor sites.
to these, there are states where a quasiparticle-quasihole pair is not on nearest-neighbor sites. Such states are called non-resonant states. For further reading, the reader can consult Ref. 33.

Here we provide a representative example to identify resonant subsystem for a system with \( L = 7 \) sites and \( N = 7 \) atoms. In this case, the neutral Mott state has one atom in each site, i.e., \([1111111] \). At \( E = U \), this state is coupled to the single dipole states \([1201111], [1021111] \), etc. These dipoles are then coupled to states with two dipole \([1201201], [1021021] \), etc. These are further coupled to states with three dipole, and so on. Note that these multiple dipole states over the Mott states are part of the resonant family. As mentioned, the non-resonant states which are not made up of nearest dipoles can be expressed as \([1012111], [1101121] \), etc. We note that the resonant and non-resonant states in the present scenario constitute a fraction of the total number of states. With this, we now aim to find the evolution of different resonant and non-resonant states in the presence of a synthetic vector potential with strength \( A_0 \), playing the role of \( E \).

\section*{C. Mechanism for HHG}

Having discussed the possible excitations in the Mott phase, we now investigate overlapping of resonant \(|\psi_{\text{res}}|^2\) and non-resonant states \(|\psi_{\text{nonres}}|^2\) with the evolved ground state \( \Psi_G(t) \) of the system for different strength of the gauge potential. Indeed, this will help us quantifying excitations responsible for HHG spectra as shown in Fig. 2. For illustration, we consider one resonant \([2011111]\), one nonresonant \([1012111]\) and one highly excited \([5200000]\) state. Fig. 5 shows the evolution of the probability of finding these states due to the application of the laser pulse. For weak strength of the potential \( A_0 \ll U \), the \(|\psi_{\text{res}}|^2\) oscillates follows the synthetic vector potential and the magnitude is very small. However, for \( A_0 \sim U \), we see enhanced \(|\psi_{\text{res}}|^2\), whereas \(|\psi_{\text{nonres}}|^2\) has an order of magnitude less contribution to the system. This is shown in Fig. 5(a). Thus the appearance of HHG can be attributed to the recombination of dipole states with the ground state at \( A_0 \sim U \). In contrast, the \(|\psi_{\text{res}}|^2\) reduces with increasing \( A_0 \), but the contribution for non-resonant state starts to dominate as evident from the blue line in Fig. 5(b). Thus, as expected, the HHG for stronger field is no longer due to the dipole states, rather the non-resonant states start to play a vital role. Apart from the resonant and non-resonant states, the excitation spectrum also consists of arbitrary highly excited states, for example, \([5200000]\). During the dynamics, the probability of contribution from these states is exceedingly low as is evident from Fig. 5(c) even when \( A_0 \approx U \). This trend is different from the behaviour of resonant and non-resonant states in the spectrum. We find similar qualitative behaviour for the other resonant, non-resonant, and highly excited states to the application of synthetic pulse with different strengths (not shown).

\section*{D. Loschmidt Echo}

To further analyze the dynamics towards the production of HHG, we turn our study to the evolution of ground state population or Loschmidt Echo i.e., \( |\langle \Psi_G(t = 0)|\Psi(t)\rangle|^2 \) for fixed \( A_0/J > 1 \) and with varying \( U/A_0 \). It is evident from Fig.6 that in the early stages of the laser pulse \( tJ \sim 0.4 \), the ground state remains unaffected, that is, the population is close to unity. When \( U = 0 \), that is, in the superfluid regime, any finite \( A_0 \) renders the single-particle wavefunction to be localized. The application of synthetic potential does not bring any substantial changes to the initial ground state. It is worth mentioning here that the effective amplitude \( A_0(t) \) reaches maxima only at the half-cycle \( (tJ = 1) \) of the pulse. In the domain \( U/A_0 < 1 \), the non-resonant states along with the resonant dipole ones start to contribute. During the period \( tJ \sim 0.4 \), the potential is weak to excite these transitions, hence the population of the evolved state does not change. For \( tJ > 0.4 \), the amplitude of the vector potential becomes effectively strong to initiate modulating the population of the ground state. The initial state at \( t = 0 \) gets deformed. As the vector potential becomes comparatively weak after the half-cycle, the system tries to relax back to the ground state giving rise to a re-entrant behaviour. We now focus our attention on the regime when \( U \sim A_0 \). The dipole formation starts around the mid-cycle, and the initial Mott state gets deformed giving rise to a decrease in the population. Following the sinusoidal nature of the pulse, we find re-entrant behaviour of the ground state. The excited state relaxes back and recombines with the ground state. It may be recalled here that \( U \sim A_0 \) is a necessary condition for the production of HHG. As \( U/A_0 > 1 \), the deformation of the initial Mott state gets plagued by weak vector potential. Hence, instead of the population going to zero, it remains as a finite quantity.

\section*{IV. CONCLUSIONS}

We have performed a detailed analysis to show that the Mott phase of the BHM admits HHG production, whereas the SF phase does not. In particular, we have demonstrated here the mechanism behind the generation of higher harmonics using intense synthetic electric field in an interacting bosonic gas loaded in an one-dimensional optical lattice. We find that the strong synthetic time-dependent vector potential manifesting itself as the synthetic electric field can generate reasonably high harmonics in the insulating regime, while the superfluid regime is transparent to it. In the insulating regime, the order and number of harmonics increase with the variation in the strength of the synthetic vector potential translating to a linear cutoff law. This is attributed to the field-driven resonant and non-resonant excitations in the neutral Mott state and their subsequent recombination with the ground state. We have shown that if the repulsive interaction between two atoms \( (U) \) is close to the strength of the potential \( (A_0) \), the resonant quasiparticle-quasihole pairs on nearest-neighbor sites play a pivotal role in generating higher harmonics. However, in the strong-field limit \( A_0 \gg U \), the nonresonant states where
FIG. 5. (Color online) Evolution of probability of finding (a) $|201111\rangle$ (single dipole state), (b) $|1012111\rangle$ (non-resonant states) and (c) $|5200000\rangle$ (highly excited state) states for varying strengths of $A_0/J$ in the Mott insulating regime with $U/J = 10$. Evidently, the evolution probability for the resonant dipole states (green curve in (a)) is found to be significant near $U/A_0 \ll 1$, whereas for $U/A_0 \gg 1$, the non-resonant state (blue curve in (b)) takes over the resonant one. The highly excited states are always suppressed (all curves in (c)) irrespective of the strength of light field.

FIG. 6. False color coded image showing the variation in Loschmidt echo $|\langle \Psi_G(t=0) | \Psi(t) \rangle|^2$ with time for a fixed value of $A_0/J$ and varying $U/A_0$. In the limit of $U = 0$, the initial ground state does not change appreciably, corroborating the localised nature of the ground state in the presence of light field. In contrast, Mott regime shows reentrant behavior due to recombination of excited states with the ground state in the presence of synthetic vector potential. This in turn leads to higher harmonics in the emitted spectra as elaborated in the main text.

We also thank the anonymous referees for their thorough review and valuable comments, which contributed to improving the quality of the manuscript.

Appendix A: Convergence check of HHG spectrum for different temporal steps of Runge-Kutta algorithm

In this appendix, we provide concrete evidence of numerical accuracy and convergence of Runge-Kutta algorithm used in this present study. For different temporal steps in Runge-Kutta algorithm, the HHG spectrum in Fig. 7 is found to fall on top of each other, justifying the accuracy and convergence of the dynamical behavior.

Appendix B: Dependence on system size

We provide here additional results to support that our calculations are devoid of any finite size effects for the case $U/J = 10$ and $A_0/J = 10$. As mentioned before, we used ED for our computations and going beyond the configuration with 9 particles and 9 sites is computationally expensive. In view of this we would also like to point out that the generation of HHG in these systems are due to strong correlation and not mean-field in nature, therefore to describe it one requires a full diagonalization of the system. This restricts the system sizes that we could access due to the exponential growth.

quasiparticle-quasihole pairs are not located on the nearest-neighbor sites contribute to higher harmonics. Finally, we have indicated a possible experimental scope of the obtained results. In the future, investigation of HHG generation in square lattices would be a natural choice; where identifying and understanding dipole states in higher dimensions is itself a topic of fundamental importance. We believe that on one hand, the creation of a near Mott insulator and on the other, the experimental feasibility to study strong-field ionization in ultracold atoms would make it feasible to study analogous HHG by bosons and its variants related to strong field physics in the near future.

Evidently, the plots for different configurations match well with other, justifying that our results are independent of system sizes.

of the Hilbert space. Nevertheless, this is the state of the art calculation and there also exist further works using exact diagonalization\(^{39,80}\) (and complementing it with Density Matrix Renormalization Group (DMRG) Ref. 51) in bosonic model, where also convergence seems to be achieved within similar system sizes revealing qualitatively identical physics. All these give us confidence that our results will be valid in the thermodynamic limit.
