Introduction

Ebola virus disease (EVD) is an extremely infectious disease and can be fatal to humans [1,2]. The virus spreads through direct contact with an infected person or their bodily fluids (through broken skin, mucus, fluids, and contaminated objects such as syringes or needles). The Ebola vaccination is expected to be the most promising treatment for preventing an Ebola outbreak.

Ebola vaccine candidates have been developed in the last decade, but none have yet been approved for clinical use. During 2014-2015, trials of candidate vaccines for EVD were fast-tracked in response to the unprecedented EVD epidemic in West Africa. Interim results from the Guinea Ebola ring vaccination trial suggested that the vaccine could have a high level of efficacy [3-5]. Rings, i.e., closest contacts of newly infected cases, defined as the contacts, and contacts of contacts, of those confirmed EVD cases, gave a cluster of contacts. A modeling study [6] suggested that implementation of a ring vaccination strategy could supplement case isolation and contact tracing, to reduce transmission. However, if there were many cases not in the known transmission chains, as in West Africa in early 2014, the results of a stochastic model [7] using individual-level transmission data suggest that ring vaccination might be insufficient to contain the outbreak, and mass vaccination or hybrid strategies involving mass and
ring vaccination, might need to be considered. It has been reported that using a spatially explicit agent-based model of EVD transmission (in a region of Sierra Leone), numerical estimates for the effectiveness of ring vaccination by varying the ring definition (contacts, contacts of contacts, and spatial components), as well as the performance of ring vaccination assuming different levels of reproduction number and contact tracing [8]. However, the efficacy of this, and the likely impact on a large, Ebola epidemic such as in West Africa, remains unclear. Simulation and forecasting of the impact of different vaccination strategies may provide important information in developing public health strategies.

In this paper, the SEIHFR epidemic model [9,10] was modified to study the spread of Ebola by intervention (vaccination) and incorporating contact tracing [11,12]. Different from the ring vaccination model [6], the effectiveness of vaccination is modeled to directly reduce the numbers of susceptible people in a population. A thorough mathematical analysis of the SEIHFR model was conducted and the transmission rates due to contact in the community, hospitals, and funerals, as well as the intervention time to best fit the data of the 2014 Ebola outbreak in Liberia were estimated. Based on the fitted model, a sensitive analysis on the scenarios of different levels of vaccination to Ebola in Liberia 2014 was performed while keeping other parameters. The threshold of the percentage of the initial vaccinated population to cease the Ebola outbreak was determined. From numerical simulation, it was calculated that if more than 48.74% of the population in Liberia were immunized, the effective reproduction number would be less than 1 and the outbreak would be under control. Some comments are made to improve the vaccination effectiveness for the randomized mass vaccination strategy and ring vaccination strategy. Although it is well known that the time to intervention is an important parameter, the scenario analysis on intervention time provides some quantified information for controlling the size of an epidemic.

Mathematical Models and Stability Analysis

There are many studies on Ebola outbreaks, with some using mathematical modeling [12-19]. Through mathematical modeling of the epidemiological distribution and transmission pattern of EVD during the African outbreak, many useful insights can be obtained to determine how these intervention measures affect the total number of infected individuals. This would lead to the development of more effective control and prevention measures for future outbreaks. Different mathematical models have been studied to provide valuable information for better understanding of EVD outbreaks, for example the SEIR model (Susceptible, Exposed, Infective, Removed) [20], the SEIHFR model (Susceptible, Exposed, Infective, Hospitalized, Funeral, Removed) [9,10,21] and many others [12,13,17-19,22]. These models use Ebola data to identify the parameters involved in transmission rates, to estimate the average number of secondary infections generated by a typical infected case, in its entire period of infectiousness, in a completely susceptible population, and this quantity is called the basic reproduction number which is denoted $R_0$. These constructed models were well fitted and were demonstrated to be effective for predictions. However, the different transmission patterns of infectious diseases could be due to the unique settings of transmission in the community, in the hospital, during burial ceremonies, and due to the availability of licensed Ebola virus vaccines as well as pre- and post-exposure treatments.

Fisman et al [16] used a simple, 2 parameter mathematical model of epidemic growth and control to estimate $R_0$ which was between 1.6 and 2.0 at the early stages of the 2014 Ebola outbreak in Liberia. Althaus [13] applied a SEIR model with time-dependency of the reproduction number, to capture the effects of control interventions by using the data of each country in West Africa from March 2014 to August 2014. $R_0$ was estimated to be 1.51 for Guinea, 2.53 for Sierra Leone and 1.59 for Liberia. Gomes et al [17] used the Global Epidemic and Mobility Model to evaluate the risk of international spread, and the basic reproduction number ranged from 1.5 to 2.0.

Moreover, Rivers et al [21] used World Health Organization (WHO) data from Liberia and Sierra Leone between March to October 2014, to parameterize a SEIHFR model, following the same model by Legrand et al [10]. They used this model to forecast the progression of the epidemic up to December 2014, as well as forecasting the efficacy of several interventions including increased contact tracing, improved infection control practices, and the use of a hypothetical pharmaceutical intervention to improve survival in hospitalized patients. There have been studies [2,14,23] and a review [24] that have presented epidemiological parameter estimates of the 2014 Ebola outbreak in West Africa.

1. SEIHFR model

The SEIHFR model has been widely cited [10]. Its underlying assumptions are made regarding the relationship between the overall waiting time in the infectious state, and the waiting times from onset to hospitalization, recovery without hospitalization, and death without hospitalization. These assumptions have been reviewed in detail [9,11] and a simpler model, which is equivalent to the Legrand model is proposed [9]. The SEIHFR model consists of the following compartments of populations in time t (Figure 1).

The “ring vaccination” strategy involves vaccinating anyone
Figure 1. Schematic diagram of the model compartments and variables.

who has come into contact with a person infected with Ebola, as well as contacts of theirs. This strategy was used in an experimental Ebola vaccination in Guinea in March 2016 and was found to be highly effective in preventing Ebola infection [7,8,25]. Vaccination was incorporated into the SEIHFR model framework by deriving a link between vaccination and contact tracing. The Contact tracing process for Ebola consisted of 3 basic elements; contact identification, contact listing and contact follow-up [11]. In order to model this process, the following assumptions were made in addition to the base SEIHFR model. Reported cases from infectious, hospitalized or contaminated deceased cases, triggered contact tracing and ring vaccination. In addition, the reported cases that triggered ring vaccination were not removed from their corresponding cases, but ring vaccination was applied to contacts and contacts of contacts. The probability \( \zeta \) accounted for unreported cases and reported cases that did not trigger contact tracing and ring vaccination. The probability \( 1 - \zeta \) accounted for the reported cases that triggered ring vaccinations and no secondary cases that were caused by them.

The number of susceptible individuals removed due to ring vaccination at time \( t \) has the following formula:

\[
\phi_2 \times \phi_1 \times (1 - \zeta) \times \frac{S}{N}(I + H + F).
\]

\( \phi_1 \) is the average number of contacts traced per reported case that triggered contact tracing.

\( \phi_2 \) is the rate of vaccination and/or isolation of the traced contacts.

\[
\nu = \phi_2 \times \phi_1 \times (1 - \zeta)
\]

is the average number of removal susceptible individuals who were successfully traced/vaccinated/isolated per reported case. The total removal number is in the mass-action form \( \frac{S}{N} \) to avoid negative compartments.

In this context, a paradigm for the process of ring vaccination was considered: 1) identification of contacts and contacts of contacts of reported cases that triggered a ring vaccination; 2) vaccination of contacts and contacts of contacts where no secondary cases were caused by these contacts. This requires a high standard in public health work for contact tracing, isolation, community engagement and availability of effective vaccines [7]. Although \( \nu \) and \( \zeta \) are not independent of each other, \( \nu \) can have different values for same \( \zeta \) due to the variables \( \phi_1 \) and \( \phi_2 \); scenarios analysis can be conducted based on the values \( \nu \) and \( \zeta \) to find out the impact of vaccination.

The only way a person can leave the susceptible group is to become infected or immunized. The only way a person can leave the infected group is to be hospitalized/recovered/removed from the disease. Once a person has recovered, the person has immunity. The SEIHFR model is as follows:

\[
\frac{dS}{dt} = -\frac{\zeta}{N}(\beta IS + \beta_H SH + \beta_F SF) - \nu S(I + H + F),
\]

\[
\frac{dE}{dt} = \frac{\zeta}{N}(\beta IS + \beta_H SH + \beta_F SF) - \alpha E,
\]

\[
\frac{dI}{dt} = \alpha E - \gamma I,
\]

\[
\frac{dH}{dt} = \gamma_H \theta_1 I - \omega H,
\]

\[
\frac{dF}{dt} = \gamma_d(1 - \theta_1)\delta_1 I + \gamma_d\delta_2 H - \gamma_F F,
\]

\[
\frac{dR}{dt} = \gamma_d(1 - \theta_1)(1 - \delta_1)I + \gamma_d(1 - \delta_2)H + \gamma_F F + \nu S(I + H + F).
\]
Table 1. Epidemiological parameters for Ebola virus disease used in this study.

| Parameter | Description                                                | All countries | Guinea | Liberia | Sierra Leone | Ref. |
|-----------|------------------------------------------------------------|---------------|--------|---------|--------------|------|
| $1/\alpha$ days | incubation period                                      | 11.4          | 10.9   | 11.7    | 10.8         | [2]  |
| $1/\gamma_h$ days | symptom onset to hospitalization                       | 5             | 5.3    | 4.9     | 4.6          | [2]  |
| $1/\gamma_r$ days | symptom onset to hospital discharge                      | 16.4          | 16.3   | 15.4    | 17.2         | [2]  |
| $1/\gamma_d$ days | symptom onset to death                                  | 7.5           | 6.4    | 7.9     | 8.6          | [2]  |
| $1/\gamma_f$ days | infectious period between death and burial               | 2             | 2      | 2       | 2            | [2]  |
| $\delta$ % | Proportion of infectious cases hospitalized              | 54            | 52     | 51      | 58           | [21, 23] |
| $\delta %$ | Ratio of case-fatality                                   | 70.8          | 70.7   | 72.3    | 69.0         | [2, 17] |
| $1/\gamma_h$ days | Time from hospitalization to recovery                    | 11.4          | 11     | 10.5    | 12.6         | Calculation |
| $1/\gamma_d$ days | Time from hospitalization to death                       | 2.5           | 1.1    | 3       | 4            | Calculation |
| $\theta$ % | Fraction of infected hospitalization                     | 36.8          | 38.2   | 33.9    | 36.1         | Calculation |
| $\delta_1$ % | Case fatality rate, unhospitalized                       | 52.6          | 48.7   | 57.3    | 52.7         | Calculation |
| $\delta_2$ % | Case fatality rate, hospitalized                         | 34.7          | 19.4   | 42.7    | 41.4         | Calculation |

These epidemiological parameters follow from the study of WHO Ebola Response Team [2, 23] and [10, 17]. They are consistent across the modeling literature for different outbreaks.

\[
\frac{1}{\gamma_h} = \frac{1}{\gamma_f} - 1, \quad 1/\gamma_d = 1/\gamma_f - 1/\gamma_h, \quad \theta_1 = \frac{\theta \gamma_h (1 - \delta_1) + \gamma_2 \delta_2}{\theta \gamma_h (1 - \delta_1) + \gamma_2 \delta_2 + (1 - \theta) \gamma_2}.
\]

The $1/\gamma_h$ is the mean duration between onset of symptoms and hospitalization. The $1/\gamma_r$ is the mean duration of the infectious period for patients who survived their illness. The $1/\gamma_d$ is the mean duration of the infectious period for patients who died. The $1/\gamma_f$ is the mean duration of the infectious period between death and burial. $\theta_1$ is computed in order that $\theta$% of infectious cases are hospitalized. $\delta_1$ and $\delta_2$ are computed to obtain a case fatality ratio at $\delta_1 \frac{1}{\gamma_h} = \frac{1}{\gamma_f} - \frac{1}{\gamma_d}$ and $\delta_2 \frac{1}{\gamma_h} = \frac{1}{\gamma_f} - \frac{1}{\gamma_d}$. Table 1 shows more information about the parameters and more details of derivation of these differential equations have been previously described explaining distribution of people across different paths [9, 21].

The “randomized mass vaccination” strategy can be used before an Ebola outbreak. By vaccinating a percentage of whole population randomly (have the same interaction with the vaccinated and non-vaccinated population), the initial susceptible population decreases and it reduces the force of infection (rate at which a susceptible person becomes infected). Let $(1-\nu)$ be the percentage of whole population that was initially vaccinated randomly before an Ebola outbreak. Scenarios analysis was conducted based on the percentages of the initial vaccinated population. This parameter does not occur in the differential equations but does in the initial values. A threshold for the parameter was deduced to make the basic reproduction number less than 1.

The cumulative number of all Ebola cases, and the cumulative number of deaths of Ebola cases respectively from the time of onset of symptoms. These 2 cumulative data were reported by the WHO. The differential equations are:

\[
\frac{dC_a}{dt} = \alpha E. \quad (7)
\]

\[
\frac{dC_d}{dt} = \gamma_d (1 - \theta_1) \delta_1 I + \gamma_{dh} \delta_2 H. \quad (8)
\]

To measure the number of vaccines needed in the ring vaccination, another recording variable $C_v(t)$ was used to keep track of the cumulative number of vaccinations.

\[
\frac{dC_v}{dt} = \nu \frac{S}{N} (I + H + F). \quad (9)
\]

Note that ring vaccination is a spatial phenomenon. A spatially explicit agent-based model [8] is calibrated to reproduce the most important features of the EVD outbreak in Pujehun district, Sierra Leone. The process of ring vaccination requires the identification of contacts and contacts of contacts of a reported case. The modified SEIHFR model cannot possibly be faithful to the process as understood by field epidemiologists. However, it can provide a numerical estimate of the effectiveness of vaccination strategies for the EVD outbreak in Liberia or other countries.
2. Mathematical analysis of the SEIHFR model

Prior to the use of the SEIHFR model to study the 2014 Ebola outbreak in West Africa, a mathematical analysis was conducted on the model. It proved that there always exists a non-negative bounded solution of the differential equation model for any non-negative initial condition. The mathematical formula for basic reproduction number \( R_0 \) was dependent on the effectiveness of vaccination \( \xi \) and \( \mu \), and it can be decomposed into 3 parts due to transmission rate in the community, after hospitalization, and during traditional burial.

\[
R_0 = \frac{\zeta}{\Delta} \beta_t + \frac{\rho \mu \beta_t}{\Delta H} + \frac{\mu S}{\gamma} \beta_F \equiv R_{0H} + R_{0H} + R_{0F}. \quad (10)
\]

By Routh-Hurwitz Criteria, a disease-free equilibrium is linearly stable when the basic reproduction number \( R_0 \) is less than 1 (Appendix).

Results on 2014 Ebola outbreak in Liberia

Ebola was first detected in 1976 when there were 2 simultaneous outbreaks in Nzara, Sudan and Yambuku, Democratic Republic of the Congo. It later occurred in a village near the Ebola River which gave its name to Ebola. Ebola has caused at least 21 confirmed outbreaks between 1976 and 2016 [1]. The 2014 Ebola epidemic in West Africa was the largest ever recorded. Ten countries in 3 continents (Africa, Europe and North America) had confirmed cases. According to the WHO situation report (Data up to March 27, 2016), 28,646 confirmed, probable, and suspected cases were reported, primarily in Guinea, Liberia, and Sierra Leone, with 11,323 deaths since the onset of the Ebola outbreak [26]. The majority of these cases and deaths were reported between August and December 2014, after which case incidence began to decline as a result of the rapid scale-up of treatment, isolation, and safe burial capacity in Guinea, Liberia, and Sierra Leone. While previous outbreaks in small villages have come to an end due to local depletion of susceptible individuals, this epidemic spread across entire countries, and thus could only be curtailed by interventions aimed at reducing new infections across all locations [14]. Organizations such as the World Health Organization (WHO) and local governments implemented intervention measures to try to control the outbreak and bring it to an end as soon as possible. While some of these interventions were simple, such as the deployment of health care workers and personal protective equipment, other interventions required much more coordination and strategy, such as establishing cross-border coalitions for the dissemination of intelligence regarding the outbreak. Among these intervention measures, the “70-70-60” plan [27,28] which aimed to isolate and treat 70% of infected individuals, and safely bury 70% of deceased individuals, within 60 days, affected a major reduction in the spread of the EVD epidemic.

In this study the SEIHFR model was used to analyze the 2014 Ebola outbreak in Liberia. Although immunization (in the context of an outbreak or epidemic) has the attractive property of reducing the force of infection, and several candidate Ebola vaccines had been produced, no vaccines had been approved for clinical use during the 2014 outbreak. However, the potential impact of a vaccination for Ebola needs to be studied to provide insights for future planning [4-8]. Fisman et al [15] studied the projected impact of vaccination timing and dose availability, and they predicted that an effective vaccination rate could be projected to prevent tens of thousands of deaths, if vaccination could be used before the epidemic peaked. This estimation of the effective vaccination rate was also discussed in another study [29]. It is reasonable to assume \( \nu = 0, \xi = 1 \) and \( \mu = 1 \) to use the SEIHFR model to study the 2014 Ebola outbreak in West Africa. The least-squares can be used to fit the data from the WHO to estimate the epidemic parameters. The fitted model can then be used to estimate the basic reproductive number \( R_0 \) and to evaluate the impact of intervention measures on the transmission rate of the disease. In this study the fitted model was used to simulate the impact of vaccination.

1. The transmission rate and the impact of interventions

Various intervention strategies [27,28,30] including surveillance, quarantine, education and rapid burial have been employed to control an outbreak and bring it to an end as soon as possible. The impact of the intervention plan such as “70-70-60” plan is not instantaneous [20]. The net effect of intervention strategies, is to reduce the transmission rate \( \beta \) (including \( \beta_t, \beta_H, \beta_F \), in our model) from \( \beta_o \) to \( \beta_i < \beta_o \). Between the time of onset of the intervention, to the time of full compliance, the transmission rate is assumed to decrease gradually from \( \beta_o \) to \( \beta_i \), according to:

\[
\beta(t) = \begin{cases} 
\beta_0, & t < T_0, \\
\beta_1 + (\beta_0 - \beta_1)e^{-q(t-T_0)}, & t \geq T_0,
\end{cases}
\]

where \( T_0 \) is the time at which interventions start, and \( q \) controls the rate of transition from \( \beta_o \) to \( \beta_i \). The larger \( q \), the faster \( \beta_o \) decays to \( \beta_i \).

2. Model parameters

The parameters in the model were put into 2 categories,
epidemiological and model. Epidemiological parameters are those which characterize the Ebola virus, such as incubation period and case-fatality ratio. They are consistent across the modeling literature for different outbreaks [10,17] and are listed in Table 1. These epidemiological parameters followed the WHO Ebola Response Team study [2,23]. The case-fatality ratio in Liberia was 0.7234 before intervention and 0.3844 after intervention.

\[ \Psi = (\beta_{\theta0}, \beta_{\theta1}, \beta_{\theta0}, \beta_{\theta1}, \beta_{\theta0}, \beta_{\theta1}, T_0, q) \]

The model parameters shown in Table 2 were fitted to the 2014 Ebola outbreak in Liberia by least-squares fit to the cumulative number of cases \( C_\alpha (t, \Psi) \) in equation (7). The nonlinear least-squares solver “lsqnonlin” in Matlab 2016b was used and appropriate initial values for the differential equations were chosen to feed the optimization process so that the “best fit” can be determined. The optimization process was repeated by feeding different initial conditions before the “best fit” was chosen. The confidence interval was computed following the method described by Chowella et al [20].

The asymptotic variance-covariance \( AV(\Psi) \) of the least-squares estimate was

\[ AV(\hat{\Psi}) = \sigma^2 \left( \sum_{i=1}^{n} \nabla C_\alpha(t_i, \Psi_0) \nabla C_\alpha(t_i, \Psi_0) \right)^{-1} \]

which was estimated by

\[ \hat{\sigma}^2 \left( \sum_{i=1}^{n} \hat{\nabla} C_\alpha(t_i, \hat{\Psi}_0) \hat{\nabla} C_\alpha(t_i, \Psi_0) \right)^{-1} \]

where \( n \) is the total number of observations, \( \sigma^2 = \frac{1}{n-\nu} \sum (y_i - \hat{C}(t_i, \Psi))^2 \) and \( \nabla C \) are numerical derivatives of \( C \). To compute the confidence intervals, \( F \)-distribution for small samples was used. Formally, the confidence intervals were of the form:

\[ \{ \Psi : \frac{\sum (y_{ai} - C_\alpha(t_i, \Psi))^2}{\sum (y_{ai} - C_\alpha(t_i, \hat{\Psi}))^2} \leq A_{\alpha} \} \]

where \( y_{ai} \) is the observed cumulative number of cases, and \( A_{\alpha} \) is the \( 1-\alpha \) quantile of an \( F \)-distribution with appropriate degrees of freedom. To have a better approximation to both the cumulative number of cases and the cumulative number of deaths, least-squares could be applied to the 2 cumulative numbers, that is, where \( y_{ai} \) was the observed cumulative number of deaths.

\[ \min_{\Psi} \sum_{i} \left( (y_{ai} - C_\alpha(t_i, \Psi))^2 + (y_{ai} - C_\alpha(t_i, \Psi))^2 \right) \]

Confidence intervals were computed by fixing all other parameters and parameters estimates are given in Table 2. There were many different parameter combinations which fitted; thus, confidence intervals may not be relevant for these purposes. For example, the 95% confidence interval \((6.1513, \infty)\) for \( q \) was not “sharp” because it covered an infinity range. This was due to the exponential decay \((e^{-q(t-T_0)}\) for \( t > T_0 \)\) of time and its value would not change much when \( q \) is large.

3. Ebola outbreak in Liberia

Data were retrieved from the WHO website, and was based on the cumulative total numbers of total cases and total deaths. The data were recorded by days and used to fit the model chosen in an interval around a whole week. The total population size \( N = S + E + I + H + F + R \) was assumed to be 4,345,000 in Liberia in 2014. Note that the exact population size does not need to be known to estimate the model parameters as long as the number of total cases was relatively small. In fact, the true mass-action assumption \( \frac{S}{N} \) was used which made the model parameters independent of \( N \). In Liberia, the cases that were reported on June 2, 2014 were the first new cases since April 7, 2014. To fit the model for Liberia, the starting date was June 2, 2014 with 19 confirmed total cases and 9 confirmed total deaths, which were used as the initial values \( C_\alpha (0) \) and \( C_\alpha (0) \). By using the optimization tool “lsqnonlin” in Matlab R2016b, parameters were estimated (Table 2). The deterministic model fitted well for Liberia (Figure 2).

4. A scenario analysis on the vaccination

In the fitted base model in this study, \( \nu \) (the average number of removals [susceptible individuals away due to vaccination] per infected case) was assumed to be 0. (1-\( \zeta \)) (the reducing rate of infected cases due to vaccination) was assumed to be 0 (\( \zeta = 1 \)), and \( \mu \) was assumed to be 1 (no randomized vaccination before Ebola outbreak). The potential impact of vaccination against Ebola was evaluated under different assumptions around the values \( \nu, \zeta \) and initial percentage (1-\( \mu \)) of the vaccinated population, while keeping the other estimated parameters the same.

5. Randomized mass vaccination before Ebola outbreak

Formula 17 (Appendix I) for the basic reproduction number \( R_0 \):

\[ R_0 = \frac{\zeta \mu}{\Delta \beta_I} + \frac{\zeta \mu \delta}{\Delta_1 \Delta_h} \beta_H + \frac{\zeta \mu \delta}{\gamma_f} \beta_F \]
which indicates that if sufficient fractions of population are immunized, the Ebola epidemic should not happen. In the appendix, it was shown that the disease epidemic was predicted to decline when $R_0 < 1$, and the disease spread would increase when $R_0 > 1$. By corollary 5.4, when random and continuous vaccination strategies for susceptible population were undertaken, the minimum effective vaccination rate $r_v = \frac{R_0 - 1}{R_0}$ and the Ebola epidemic, would be under control if the initial vaccinated rate of the total population was greater than $r_v$. According the estimated value in this study (Table 2), if $1 - \mu > 48.74\%$ or $\mu < 51.25\%$, the number of new cases would decline from the very beginning (Figure 3 right) and the Ebola outbreak in Liberia would be under control (Figure 3 left). Based on the estimates of the basic reproduction number in [2], it was estimated that the minimum effective vaccination rates and the Ebola outbreak would be under control if $> 41.52\%$ and $> 50.50\%$ of the total population were vaccinated in Guinea and Sierra Leone, respectively. These predictions provide scientific evidence of the need for vaccine production and application. For purposes of simplicity, the assumption was made that the vaccine was 100% efficacious with a single dose required for immunity. Roughly

| Parameter | Description | Fitted value Liberia |
|-----------|-------------|----------------------|
| $\beta_{r0}$ | Transmission rate in the community before intervention | 1.2596 |
| $\beta_{r1}$ | Transmission rate in the community after intervention | 0.3988 |
| $\beta_{h0}$ | Transmission rate after hospitalization before intervention | 1.1338 |
| $\beta_{h1}$ | Transmission rate after hospitalization after intervention | 0.4418 |
| $\beta_{b0}$ | Transmission rate during traditional burial before intervention | 0.9794 |
| $\beta_{b1}$ | Transmission rate during traditional burial after intervention | 0.4566 |
| $T_o$ | Duration from beginning of epidemic to invention taken place | 14.8057 |
| $q$ | Measure the speed of transition from $\beta_0$ to $\beta_1$ | 36.8342 |
| $R_0$ | Basic reproduction number | 1.9508 |

Figure 2. Fitted line with World Health Organization data for Ebola Epidemic in Liberia. The solid red line represents the deterministic model fit of the epidemic in Liberia. The green star represents the actual data from World Health Organization. The start date was June 2, 2014.
speaking, nearly 2.1 million highly effective vaccines are needed to prevent an Ebola outbreak. Real-world vaccination would require more doses of vaccines if the efficacy of the vaccine was less than 100%. Mass vaccination may impose lots of challenges to the countries, cities and families affected. Financial challenges and ethical challenges would be associated with the implementation of wide-scale vaccination with a new Ebola vaccine that had been fast tracked with limited evaluations for safety and efficacy, however a benefit risk assessment would be made.

The impact of a small percentage of the population being vaccinated initially was explored. It was observed that this can also substantially reduce the final size of the Ebola epidemic if current interventions were maintained (Figure 4). The initial vaccinated population that reduced the initial susceptible population by 1%, 5% or 10% resulted in a corresponding reduction of the final total case by 8.8%, 36.5%, 59.1%, and a reduction of the final total deaths by 8.2%, 34.2%, and 56.2% respectively. The epidemic would also end sooner with larger fractions of the population immunized. The significance of a reduction of the final epidemic size would make vaccination a highly attractive intervention to help control this epidemic.
6. Continuous Ring Vaccination

The ring vaccination strategy (that involves vaccinating anyone who has come into contact with a person infected with Ebola, as well as contacts of theirs) was modeled. This strategy was used in an experimental Ebola vaccine in Guinea in March 2016 and was found to be highly effective in preventing Ebola infection. Some evaluations and analysis on the efficacy of the vaccination have been studied [4-8,25]. The parameter $\nu$ models the average required number for vaccinating contact persons per infected person, and the parameter $\zeta$ models the direct impact of ongoing vaccination/isolating on the transmission rate. In this study the impact on the epidemic due to these 2 parameters while keeping all other parameters/interventions the same was investigated.

In this study it was assumed that there was a small direct reduction on the transmission rate ($\zeta = 0.99$). The cumulative number of infected cases was reduced as the parameter $\nu$ increased from $\nu = 0, 20, 40, 60, 80$ to 100 (Figure 5). Although the SEIHFR model did not randomize mass vaccination during the course of the Ebola outbreak, the vaccination strategy in this case could be treated as a randomized mass vaccination strategy rather than a ring vaccination strategy. However, the impact on the reduction of the total number of cases was not significant, compared with the total number of vaccinations needed in the case of a randomized mass vaccination that was used before the Ebola outbreak. In this case, about 200 vaccines would be needed to decrease 1 infected case. When $\nu = 100$, about 1.02 million (23% of total population) vaccines would be used, but this could only reduce the number of infected cases by approximately 3,219 (34% of the total infected cases). This is far below the ratio where 10% of the initially vaccinated population would reduce 59.1% of potentially infected cases. This implies that vaccination should be given as soon as possible if a randomized strategy is used.

As shown in an experimental Ebola vaccination in Guinea in March 2016, the ring vaccination strategy would be effective at preventing Ebola infection. To see how the reduction rate changes the epidemic case, $\zeta$ was assumed to be zero in this numerical simulation. Figure 6 shows that the reduction rate that decreased by 5% ($\zeta = 0.95$), 10% ($\zeta = 0.90$), 20% ($\zeta = 0.80$)
would result in a corresponding reduction of infected cases by 36.5%, 59.1%, and 82.4%, and a reduction of total deaths by 33.1%, 56.2%, and 80.0%, respectively. The higher the reduction rate, the smaller the cumulative number of infected cases was, and the quicker the epidemic would end.

By carefully tracing the contact persons of an infected person the average number of vaccinations given per cluster of infected persons would increase and it is assumed that the infected rate would be reduced. However, this data was not available to fit the model in this study to determine how to achieve a reduced infected rate. In this study, combination effects (Figure 7) of \((\zeta, \nu)\) at the different levels \((1.0), (0.96,20), (0.92, 40), (0.88, 60), (0.84, 80), (0.80, 100), (0.50, 200)\) were proposed. In general, the total number of vaccines would increase while \(\nu\) increased. However, when the ring vaccination strategy becomes more effective (small \(\zeta\)), the total number of vaccines could decrease while the average number of vaccines per infected person \(\nu\) increases (see right in Figure 7). With an average of 200 vaccines per infected person and a reduced rate of infection at 50%, only about 71,000 vaccines (about 1.6% of the total population) would be used, and there would be about 214 total infected cases and 145 total deaths. The outbreak would also end within 20 weeks (about October 14, 2014). This observation indicated that reducing the infection rate could be more effective in mitigating an epidemic. Therefore, the ring vaccination strategy could be a good choice if the infection rate could be reduced significantly. It depends on the level of effectiveness of contact tracing which is highly dependent on public health resources [11,12].

By the formula of the basic reproduction number \(R_0\) given in equation 17 (Appendix), it was obvious that \(R_0\) linearly depends on the level of ring vaccination \((\zeta)\), the transmission rate after hospitalization \((\beta_H)\) and the transmission rate during traditional burial \((\beta_F)\). In Figure 8, it shows that the basic reproduction number \(R_0\) was decreasing when the corresponding parameter decreased and all other parameters

![Figure 7. Ebola outbreak in Liberia with different efficiency level of ring vaccinated population, where \((\zeta, \nu)\) = \((1.0), (0.96,20), (0.92, 40), (0.88, 60), (0.84, 80), (0.80, 100), (0.50, 200)\).

![Figure 8. Dependence of the basic reproduction number \(R_0\) and some important parameters: \(\zeta, \beta_H, \beta_F\).]
were fixed. For example, the estimated basic reproduction number for the 2014 Liberia Ebola outbreak decreased from 1.9508 to 1.6795, if the transmission rate after hospitalization decreased from 1.1338 to 0.4, $R_0$ decreased from 1.9508 to 1.8310, transmission rate during traditional burial decreased from 0.9794 to 0.4 and $R_0$ decreased from 1.9508 to 0.7803, the level of not triggering a ring vaccination would decrease from 1 to 0.4. Although decreasing each parameter can reduce the basic reproduction number, only the level of ring vaccination will affect the basic reproduction number in all aspects and it can reduce the basic reproduction number to $< 1$, which will terminate the epidemic of Ebola. On the other hand, only focusing on decreasing the transmission rate after hospitalization or during traditional burial, cannot reduce the basic reproduction number to $< 1$, which means the epidemic can continue. To effectively slow/stop the spread of Ebola, combined actions have been taken to reduce the transmission rate in the community, after hospitalization and during traditional burial (prohibited during the 2014 outbreak of Ebola in Liberia).

7. A scenario analysis on the time to intervention $T_p$

From the start of the epidemic on June 2, 2014, the intervention measures would take place for 14.8 weeks, until September 12, 2014. By that time the cumulative number of cases would have already reached 2,081 total deaths, with 1,137 cases showing no signs of slowing down. After the start of the intervention, the transmission rates would start to decline and the epidemic would eventually end. This intervention time was consistent with an intervention measure implemented for Liberia by a joint declaration of governments, and it was also consistent with the “70-70-60” plan which was implemented on October 1, 2014. Figure 9 shows how a change in the intervention time affected the final size of the epidemic.

The earlier intervention, with the smaller final size (Figure 9), resulted in the intervention time starting 1-2 weeks earlier and resulted in a corresponding reduction of final total cases from 10,515 to 8,080, and 6,211, and final total deaths from 4,611 to 3,541, and 2,722 respectively. The intervention time that began 1-2 weeks later resulted in a corresponding increase in total cases from 10,515 to 13,631, 17,682, and final total deaths from 4,611 to 5,980, 7,759 respectively. Roughly speaking, 1 week change in intervention time resulted in about 23% to 30% change in its final size.

Conclusion

Many mathematical models such as the SEIR model and its variants, the stochastic model, and the spatially explicit agent-based model have been developed to study the EVD transmission under different interventions. Of the interventions modeled, the most frequently suggested intervention was a combined strategy of isolating infected individuals from the general population, and providing sufficient supplies to treat them. In this study the SEIHFR model of Ebola epidemics was extended to evaluate the potential impact of Ebola vaccination.

The data was fitted to the model in this study without vaccination ($\mu = 1, \xi = 1, \nu = 0$). According to the simulation study it fitted very well in Figure 2. The basic reproduction number decreased from 1.9058 before intervention, to 0.8456 after intervention.

A detailed analysis was carried to understand the
mathematical dynamics of the disease. The system had a disease-free equilibrium \( (S, R, E, I, H, F) = (\mu N, (1-\mu)N, 0, 0, 0, 0) \) and it was stable in its infection subsystem if the basic reproduction number \( R_0 \) was < 1. In turn, this generated a threshold for the effective vaccination rate to arrest or mitigate an epidemic.

The simulation study in Figure 3 showed that if the initial vaccination rate was larger than the threshold, then the spread of the epidemic was under control and would gradually stop. If a 100% single dose efficacious vaccine was available for immunity, nearly 2.1 million highly effective vaccines would be needed to substantially prevent an Ebola outbreak in Liberia, and nearly 49% of the total population in Liberia would need to be vaccinated before or at the beginning of the outbreak.

Simulation studies in Figures 4 and 5 showed that vaccination should be implemented as soon as possible if a randomized mass vaccination strategy was used, which is consistent with observations reported by Fisman et al [15]. The simulation study in Figure 9 showed that a delay in intervention by 2 weeks would result in a total case increase of about 68%. Early intervention and early vaccination should be implemented side-by-side to achieve the greatest effectiveness.

Reducing the infection rate was the key impact factor on vaccine administration. The model allowed quantification of the parameters corresponding to the number of vaccines \( (\nu) \) and a reduced infection rate \( (1-\zeta) \) for evaluating the impact of the vaccine policy. Simulation studies in Figures 6 and 7 showed that the ring vaccination strategy could be a good choice if the infection rate could be reduced significantly. Potentially, the most effective way may be a combined strategy of intensifying contact tracing to remove infected individuals from general populations, and vaccinating contact persons of an infected individual as well as their contacts. Even if the ring vaccination with 200 vaccines per infected person could reduce the infection rate by 50% in Liberia, the simulation study in Figure 7 showed that the outbreak would end within 20 weeks, and there would be about 214 total infected cases and 145 total deaths, which was equivalent to 2% and 3% of the current total infected cases and deaths, respectively.

Mathematical modeling is a valuable tool to understand the dynamics of infectious diseases. However, there are also limitations in applying mathematical models for Ebola outbreaks due to the complexity of real world events. It cannot be implied that a vaccine with 100% effectiveness against the Ebola virus can automatically stop an Ebola outbreak. Other intervention strategies (including accurate and timely identification and quarantine, sufficient medical care, safe burials, tracing the contact persons of an infected individual as well as their contacts), need to be implemented collaboratively.

Conflicts of Interest

No potential conflicts of interest to report that were relevant to this article.

Appendix I.

1. Mathematical analysis of the SEIHFR Model

A mathematical analysis of the SEIHFR model was conducted. It was shown that a non-negative bounded solution of the differential equation model for any non-negative initial condition always exists. The mathematical formula for basic reproduction number \( R_0 \) is generated and it can be decomposed into 3 parts due to transmission rate in the community, after hospitalization, and during traditional burial. By Routh-Hurwitz Criteria, a disease-free equilibrium is locally asymptotically stable in the infection subsystem when the basic reproduction number \( R_0 \) is less than 1.

1.1. Nonnegativity and boundedness

It is crucial to show that the solutions to the initial-value problem are non-negative and bounded and they retain the biological validity for all values of time.

Lemma 5.1. [Nonnegativity] Let \( t \geq 0 \). If the initial conditions satisfy \( S(0) \geq 0, E(0) \geq 0, I(0) \geq 0, H(0) \geq 0, F(0) \geq 0, R(0) \geq 0, \) then \( S(t) \geq 0, E(t) \geq 0, I(t) \geq 0, H(t) \geq 0, F(t) \geq 0, R(t) \geq 0 \) for all \( t \in [0, t_0] \).

Proof. By Lemma 5.1.

Lemma 5.2. [Boundedness] For any \( t \in [0, t_0] \), \( S(t), E(t), I, H(t), F(t), R(t) \) are less than \( N \).

Proof. This is a direct consequence of that \( S+E+I+H+F+R=N \) and all \( S, E, I, H, F, R \) are nonnegative.

By the Fundamental Theorem of Existence and Uniqueness for differential equations, there exists a unique, positive, and bounded solution to the ordinary differential equations given in (1) to (6).

2. SEIHFR Model in matrix form

To better understand the transmission of an infectious disease, it is important to distinguish new infections from all other changes in population. It can be shown that SEIHFR model can be written as the system below and is defined on a forward invariant compact subset \( \Omega \) of \( R^2 \times R^6 \), by Lemma 5.1 and 5.2.

\[
\begin{align*}
\frac{dS}{dt} &= -\alpha S E - \gamma_{H} I, \\
\frac{dE}{dt} &= -\gamma_{I} E - \gamma_{H} I - \nu E, \\
\frac{dI}{dt} &= \gamma_{I} E + \gamma_{H} I - \delta_1 I - \nu I, \\
\frac{dH}{dt} &= \alpha S E + \gamma_{H} I - \delta_2 H, \\
\frac{dF}{dt} &= \gamma_{H} I - \delta_3 F, \\
\frac{dR}{dt} &= \delta_1 I + \delta_2 H + \delta_3 F - \nu R.
\end{align*}
\]
where $X_i = \frac{[\mathbf{S}_i]}{[\mathbf{N}_i]}$ represents the states of different compartments of non-transmitting individuals (susceptible, recovered or immune, ……), $X_j = \frac{[\mathbf{I}_j]}{[\mathbf{N}_i]}$ represents the states of compartments of different transmitting individuals (infected, infectious, ……), and $X = \frac{[\mathbf{X}]}{[\mathbf{N}]}$.

(12) $A_1(x_2) = \left[-\frac{\beta}{N}(1+\theta_1(1-\delta_i)) + \frac{\gamma}{N}(I+H+F) \right] - \frac{\gamma}{N}(I+H+F) \right] 0 \right] \right)$

(13) $A_{12} = \left[ \begin{array}{ccc} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{array} \right]$ $A_2(x) = \left[ \begin{array}{ccc} -\alpha -\Delta_i -\Delta_0 & 0 & 0 \\ 0 & \gamma \theta_1 & 0 \\ 0 & \gamma_0 \theta_1 & 0 \end{array} \right]$ where

$\Delta_i = (\gamma_0 \theta_1 + \gamma(1-\theta_1)(1-\delta_i) + \gamma_0(1-\theta_1) \delta_i)$,

$\Delta_0 = (\gamma_0 \theta_2 + \gamma(1-\theta_1)(1-\delta_2) + \gamma_0(1-\theta_1) \delta_2)$.  

(15) $A = \left[ \begin{array}{ccc} 0 & \zeta \psi \theta \delta & \zeta \psi \theta \delta \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{array} \right] \left[ \begin{array}{ccc} \alpha^{-1} & 0 & 0 \\ 0 & \Delta_0^{-1} & 0 \\ 0 & 0 & \Delta_0^{-1} \end{array} \right] \left[ \begin{array}{ccc} 0 & \zeta \psi \theta \delta & \zeta \psi \theta \delta \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{array} \right] \left[ \begin{array}{ccc} \alpha^{-1} & 0 & 0 \\ 0 & \Delta_0^{-1} & 0 \\ 0 & 0 & \Delta_0^{-1} \end{array} \right]$

The formula for $R_0$ is the spectral radius of the next generation matrix (the maximum value of its eigenvalues) and

(16) $R_0 = \frac{\zeta \psi \theta \delta}{\delta \psi \theta \delta} \frac{2 - \psi \theta \delta}{2 - \psi \theta \delta}$.

Note, from the definition in Table 1, $\delta_i = \frac{\psi \theta \delta}{\delta \psi \theta \delta(1-\delta_i)}$, one can obtain

$\delta = \frac{\delta_2 \psi \theta \delta}{(1-\delta_2) \psi \theta \delta + \delta_1 \psi \theta \delta} = \frac{\delta_2 \psi \theta \delta}{\delta_1 \psi \theta \delta}$

Because $\delta = \frac{\psi \theta \delta}{\delta \psi \theta \delta}$ in Table 1, we have $\frac{\delta_i}{\delta} = \frac{\psi \theta \delta}{\delta \psi \theta \delta(1-\delta_i)}$, which is equivalent to:

$\gamma_0 \theta_1 (1-\delta) - \gamma_0 (1-\theta_1) \delta = 0$.

By direct computation, we have:

$\Delta_i \psi \theta_1 (1-\theta_1) + \gamma_0 \theta_1 \gamma_0 \theta_2 \delta - \gamma_0 \theta_1 \gamma_0 \theta_2 \delta_2 = \frac{\Delta_i \psi \theta_1 (1-\theta_1) + \gamma_0 \theta_1 \gamma_0 \theta_2 \delta - \gamma_0 \theta_1 \gamma_0 \theta_2 \delta_2}{\Delta_i}$

$\Delta_0 \psi \theta_1 (1-\theta_1) + (\Delta_i - \gamma_0 (1-\theta_1)(1-\delta_i) - \gamma_0 (1-\theta_1) \delta) \Delta_0$

Therefore, $R_0$ can be decomposed into 3 parts due to the transmission rate in the community, after hospitalization, and during traditional burial.

(17) $R_0 = \frac{\zeta \psi \theta \delta}{\delta \psi \theta \delta} + \frac{\zeta \psi \theta \delta}{\delta \psi \theta \delta} + \frac{\zeta \psi \theta \delta}{\delta \psi \theta \delta} = R_1 + R_2 + R_3$.

4. Equilibrium, stability and immunity

The SEIHF model has equilibrium points which belong to the line segment

(18) $L = \{(S^*, R^*, 0, 0, 0, 0) : S^* \geq 0, R^* \geq 0, \text{ and } S^* + R^* = N\}$.

Note that the system only has disease free equilibria and it has no coexistence equilibrium.
Theorem 5.3. Let \( P_0 = (X_0^*, 0) = (\mu N, (1-\mu)N, 0, 0, 0, 0) \in L \) be a disease-free equilibrium, where \( \mu \in [0,1] \). Then \( P_0 \in L \) is a locally asymptotically stable disease-free equilibrium in the infection subsystem if the basic reproduction number \( R_0 \) for \( P_0 \) is less than 1. Conversely, \( P_0 \in L \) is an unstable disease-free equilibrium if the basic reproduction number \( R_0 \) for \( P_0 \) is greater than 1.

Proof. The Jacobian for the linearized system of the SEIHFR model along the equilibrium \( P_0 \) is

\[
J = \begin{bmatrix}
0 & 0 & 0 & -(\zeta \beta + \nu) & -\zeta \beta \mu & -\zeta \beta \nu \\
0 & 0 & 0 & \gamma (1-\theta_1)(1-\delta) + \nu & \gamma (1-\delta_2) + \nu & \gamma + \nu \\
0 & 0 & 0 & \alpha \zeta \beta & \zeta \beta \mu & \zeta \beta \nu \\
0 & 0 & 0 & \alpha - \Delta & -\Delta & 0 \\
0 & 0 & 0 & 0 & \gamma \theta_1 & -\Delta_0 \\
0 & 0 & 0 & \gamma (1-\theta_1) \delta_1 & \gamma \alpha \delta_2 & -\gamma
\end{bmatrix}
\]

and its characteristic polynomial is

\[
J(\lambda) = \lambda^7(\lambda^3 + B_3 \lambda^3 + B_2 \lambda^2 + B_1 \lambda + B_0),
\]

where

\[
B_0 = -\zeta \beta \alpha \Delta_1 \gamma - \zeta \beta \alpha \gamma \theta_1 \gamma - \gamma \theta_1 \gamma \theta_1 \alpha \zeta \beta \mu - \gamma (1-\theta_1)(1-\delta) \alpha \zeta \beta \mu \Delta + \alpha \Delta \Delta \gamma, \\
B_1 = -\zeta \beta \alpha \Delta_1 \gamma - \zeta \beta \alpha \gamma \theta_1 \gamma - \gamma \theta_1 \gamma \theta_1 \alpha \zeta \beta \mu - \gamma (1-\theta_1)(1-\delta) \alpha \zeta \beta \mu \Delta + \alpha \Delta \Delta \gamma, \\
B_2 = -\zeta \beta \alpha \Delta_1 \gamma - \zeta \beta \alpha \gamma \theta_1 \gamma - \gamma \theta_1 \gamma \theta_1 \alpha \zeta \beta \mu - \gamma (1-\theta_1)(1-\delta) \alpha \zeta \beta \mu \Delta + \alpha \Delta \Delta \gamma, \\
B_3 = -\zeta \beta \alpha \Delta_1 \gamma - \zeta \beta \alpha \gamma \theta_1 \gamma - \gamma \theta_1 \gamma \theta_1 \alpha \zeta \beta \mu - \gamma (1-\theta_1)(1-\delta) \alpha \zeta \beta \mu \Delta + \alpha \Delta \Delta \gamma, \\
B_4 = \gamma \Delta + \alpha + \Delta.
\]

The characteristic polynomial has eigenvalue zero and the equilibrium is not linearly stable for the whole system. But the characteristic polynomial of its infection subsystem is:

\[
P = \lambda^3 + B_3 \lambda^3 + B_2 \lambda^2 + B_1 \lambda + B_0.
\]

If \( R_0 > 1, B_0 < 0 \). By Descartes’ Rule of Signs, the characteristic polynomial has at least one positive root. So, the equilibrium \( P_0 \) is linearly unstable. We will use the Routh-Hurwitz Criteria and the values of \( B_0, B_1, B_2 \) and \( B_3 \) to derive the stability of \( P_0 \). We know that all of the parameters are positive. It is clear that \( B_0 > 0, B_1 > 0, B_2 > 0, B_3 > 0 \) if \( R_0 < 1 \). We use Maple 2016 to carry out the following calculations:

\[
B_3B_2 - B_1 = (\gamma + \Delta + \alpha + \Delta)((\alpha \Delta_0 - R_0 + 1 + R_{inf} + R_{sep})) +
\]

\[
(\gamma + \Delta + \alpha + \Delta)(\Delta \Delta + \gamma + \Delta + \gamma + \gamma) +
\]

\[
(\gamma + \Delta + \alpha + \Delta)(\Delta \Delta + \gamma + \Delta + \gamma) +
\]

\[
(\gamma + \Delta + \alpha + \Delta)(\Delta \Delta + \gamma + \Delta + \gamma).\]
