ABSTRACT

We present X-ray, optical, near-infrared (IR), and radio observations of gamma-ray bursts (GRBs) 110709B and 111215A, as well as optical and near-IR observations of their host galaxies. The combination of X-ray detections and deep optical/near-IR limits establish both bursts as “dark.” Sub-arcsecond positions enabled by radio detections lead to robust host galaxy associations, with optical detections that indicate \( z \approx 4 \) (110709B) and \( z \approx 1.8–2.9 \) (111215A). We therefore conclude that both bursts are dark due to substantial rest-frame extinction. Using the radio and X-ray data for each burst we find that GRB 110709B requires \( A_V^{\text{host}} \gtrsim 5.3 \) mag and GRB 111215A requires \( A_V^{\text{host}} \gtrsim 8.5 \) mag (assuming \( z = 2 \)). These are among the largest extinction values inferred for dark bursts to date. The two bursts also exhibit large neutral hydrogen column densities of \( N_{\text{HI, int}} \gtrsim 10^{22} \) cm\(^{-2} \) (\( z = 2 \)) as inferred from their X-ray spectra, in agreement with the trend for dark GRBs. Moreover, the inferred values are in agreement with the Galactic \( A_V \sim N_{\text{HI}} \) relation, unlike the bulk of the GRB population. Finally, we find that for both bursts the afterglow emission is best explained by a collimated outflow with a total beaming-corrected energy of \( E_{\gamma} + E_{K} \approx (7–9) \times 10^{51} \) erg (\( z = 2 \)) expanding into a wind medium with a high density, \( M \approx (6–20) \times 10^{-3} M_\odot \text{yr}^{-1} \) (\( n \approx 100–350 \) cm\(^{-3} \) at \( \approx 10^{17} \) cm). While the energy release is typical of long GRBs, the inferred density may be indicative of larger mass-loss rates for GRB progenitors in dusty (and hence metal rich) environments. This study demonstrates the critical role of radio observations in establishing the origin and properties of dark GRBs. Observations with the JVLA and ALMA will provide a sample with sub-arcsecond positions and robust host associations that will help to shed light on obscured star formation and the role of metallicity in GRB progenitors.

Key words: dust, extinction – gamma-ray burst: general

Online-only material: color figures

1. INTRODUCTION

Long-duration gamma-ray bursts (GRBs) have been linked to the deaths of massive stars, and hence to star formation activity, through their association with star-forming galaxies (e.g., Djorgovski et al. 1998; Fruchter et al. 2006; Wainwright et al. 2007) and with Type Ic supernova explosions (e.g., Woosley & Bloom 2006). Across a wide range of cosmic history a substantial fraction of the star formation activity (~70% at the peak of the star formation history, \( z \sim 2–4 \)) is obscured by dust, with about 15% of the total star formation rate density occurring in ultra-luminous infrared galaxies (e.g., Bouwens et al. 2009; Reddy & Steidel 2009; Murphy et al. 2011). As a result, we expect some GRBs to occur in dusty environments that will diminish or completely extinguish their optical (and perhaps even near-IR) afterglow emission. Such events can be used as signposts for the locations and relative fraction of obscured star formation across a wide redshift range (e.g., Reichart & Price 2002; Ramirez-Ruiz et al. 2002; Tretham et al. 2002). In addition, they can provide insight into the role of metallicity in GRB progenitors since dusty environments generally require substantial metallicity (see Roseboom et al. 2012).

These so-called optically-dark GRBs are indeed known to exist (e.g., Groot et al. 1998; Djorgovski et al. 2001; Fynbo et al. 2001; Piro et al. 2002), but the lack of an optical detection does not necessarily point to dust obscuration. Most prosaically, the lack of detected optical emission may be due to inefficient follow-up observations, or to intrinsically dim events (e.g., Berger et al. 2002). Another potential origin of dark bursts is a high redshift, with the optical emission suppressed by...
Lyα absorption at $\lambda_{\text{obs}} \lesssim 1216 \, \text{Å} \times (1 + z)$ (Haislip et al. 2006; Salvaterra et al. 2009; Tanvir et al. 2009; Cucchiara et al. 2011). Such events are clearly of great interest since a dropout above $\sim 1$ μm points to $z \gtrsim 7$, while events that are also dark in the near-IR can potentially arise at $z \gtrsim 18$ (K-band dropout). Naturally, high redshift bursts will also lack host galaxy detections in the optical band. On the other hand, their afterglow emission redward of the Lyα break will follow the expected synchrotron spectrum ($F_\nu \propto \nu^{-\beta}$) with $\beta \approx 0.5$–1 (Sari et al. 1998).

To determine whether a burst is genuinely dark, due to extinction or to a high redshift rather than to an inefficient search, it is a useful diagnostic to compare the observed limits or faint detection with the expected optical/near-IR brightness expected based on the brightness of the X-ray afterglow. This approach relies on the simple power law shape of the afterglow synchrotron emission (see Sari et al. 1998). One definition of dark bursts uses an optical to X-ray spectral index of $\beta_{\text{OX}} \lesssim 0.5$ ($\beta$ is the slope of the synchrotron spectrum in log space; see Jakobsson et al. 2004 for details), since this is the shallowest expected slope in the standard afterglow model. A variant of this condition uses knowledge of the X-ray spectral index ($\beta_X$), and defines bursts as dark if $\beta_{\text{OX}} - \beta_X \lesssim -0.5$ (van der Horst et al. 2009), since this is the shallowest expected relative slope. These definitions can reveal evidence for dust extinction even if an optical afterglow is detected.

This approach of utilizing spectral slopes has been used by several groups to identify and study dark bursts, although different samples and analysis methods yield dramatically different results for the dark burst fraction and the mean extinction relative to the GRB population at large. In the pre-
Swift era, Jakobsson et al. (2004) examined 52 bursts with X-ray afterglows and identified five to be dark with $\beta_{\text{OX}} < 0.5$. However, they found another five to be potentially dark, strongly cautioning that each burst must be modeled individually and the $\beta_{\text{OX}}$ cutoff should only be used as a first order diagnostic. The overall fraction of dark bursts in the Jakobsson pre-
Swift sample is somewhere between $\sim 10$% and $20$%. To avoid selection bias, Fynbo et al. (2009) defined an X-ray-selected sample of 146
Swift bursts and constrained the dark burst fraction to be larger ($25$%–$42$%) than the $14$% dark burst fraction determined if only GRBs with spectroscopy are considered. Melandri et al. (2012) studied a complete sample of 58 bright
Swift bursts, of which 52 have known redshifts and found that the fraction of dark bursts is about $30$%, mainly due to extinction (nearly all the dark bursts in their sample have $z \lesssim 4$). Thus, the afterglow emission of $\sim 1/3$–$1/2$ of all GRBs are affected by dust, although in most cases the required extinction is modest, $A_V^{\text{host}} \approx 0.3$ mag (Kann et al. 2006, 2010; Schady et al. 2007; Perley et al. 2009; Greiner et al. 2011).

Several studies have quantified dust extinction in GRBs. Analyzing optical/IR data for 30 GRBs pre-
Swift, Kann et al. (2006) found a mean extinction of $A_V^{\text{host}} \approx 0.2$ mag, indicating that most events are not dark. Schady et al. (2007) studied several bursts with
Swift X-ray and UV/optical detections and found a mean extinction level of $A_V^{\text{host}} \approx 0.3$ mag, and that bursts that are dark blueward of V-band are likely to have rest-frame extinction about an order of magnitude larger. Melandri et al. (2008) used rapid optical observations of 63
Swift bursts and found that about $50$% showed evidence of mild extinction. A similar conclusion was reached by Cenko et al. (2009) based on rapid optical observations of 29
Swift bursts, with an $80$% detection fraction, but with roughly half exhibiting suppression with respect to the X-ray emission. A follow-up study of the latter sample by Perley et al. (2009) aimed at identifying host galaxies in the optical (thereby ruling out a high redshift origin) and found that $\lesssim 7$% of
Swift bursts are located at $z \gtrsim 7$. The majority of the dark bursts in the Perley et al. (2009) sample instead require $A_V^{\text{host}} \gtrsim 1$ mag, with a few cases reaching $\sim 2$–$6$ mag. There are only a few known cases with large extinction of $A_V^{\text{int}} \sim \text{few mag}$ (see Perley et al. 2013, with 23
Swift galaxies having $A_V > 1$). A few notable examples of highly extinguished afterglows include GRB 070306 (Jaunsen et al. 2008), GRB 080607 (Prochaska et al. 2009), and GRB 090417B (Holland et al. 2010).

Concurrent studies of the neutral hydrogen column density distribution, inferred from the X-ray afterglow spectra, suggest that dark bursts exhibit systematically larger values of $N_{\text{H, int}} \gtrsim 10^{22}$ cm$^{-2}$ compared with bursts with little or no extinction, which have a median of $N_{\text{H, int}} \approx 4 \times 10^{21}$ cm$^{-2}$ (Campana et al. 2012; Margutti et al. 2013). On the other hand, the measured extinction for GRBs is generally lower than expected based on the values of $N_{\text{H, int}}$ and the Galactic $A_V$/$N_{\text{H}}$ relation, previously attributed to dust destruction by the bright X-ray/UV emission (e.g., Galama & Wijers 2001; Schady et al. 2007; Perley et al. 2009). Furthermore, Watson & Jakobsson (2012) point out that the tendency for bursts with very high X-ray column to have dusty sight lines may introduce a bias that at least partially explains the observed trend of increasing $N_{\text{H, X}}$ with redshift. Above $z \sim 4$ there is typically less dust extinction, and so the high-$N_{\text{H, X}}$ bursts in this regime appear to require another explanation.

Finally, the host galaxies of at least some dark bursts appear to be redder, more luminous, more massive, and more metal rich than the hosts of optically-bright GRBs (Berger et al. 2007; Levesque et al. 2010; Perley et al. 2009, 2011a; Krühler et al. 2011), potentially indicating that the extinction is interstellar in origin rather than directly associated with the burst environment. One specific example is GRB 030115, not only one of the first examples of a heavily extinguished GRB afterglow, but residing in a host classified as an extremely red object (ERO; see Levan et al. 2006). More recently, Rossi et al. (2012) report seven additional potential ERO hosts. Some host galaxies of optically-bright bursts have been detected in the radio and (sub)millimeter ranges (e.g., Tanvir et al. 2004, indicating obscured star formation rates of $\sim 10^2$–$10^3$ $M_\odot$ yr$^{-1}$ (Berger et al. 2003a). This suggests that the dust distribution within the host galaxies is patchy and that not all GRBs in dusty host galaxies are necessarily dust-obscured (Berger et al. 2003a; Perley et al. 2009). Further work by Svensson et al. (2012) indicates that dark GRB host galaxies may be systematically redder and more massive than optically bright GRB host galaxies and have lower metallicity than submillimeter galaxies, leading to prior biases in GRB host galaxy population studies.

Here we present multi-wavelength observations that reveal two of the darkest known bursts to date, GRBs 110709B and 111215A. These events have such large rest-frame extinction that they lack any afterglow detection in the optical and near-IR bands (to $\lambda_{\text{obs}} \approx 2.2$ μm) despite rapid follow-up. However, both events are detected in the radio, providing sub-arcsecond positions and secure associations with host galaxies detected in the optical. This allows us to rule out a high redshift origin, while the combination of radio and X-ray data place robust lower limits on the rest-frame extinction, with $A_V^{\text{host}} \gtrsim 5.3$ and $\gtrsim 8.5$ mag (for $z \approx 2$), respectively. The radio and X-ray data also allow us to determine the expansion properties.
and the circumburst densities. This study demonstrates that radio detections with the JVLA, and soon with the Atacama Large Millimeter/submillimeter Array (ALMA), provide a promising path to accurate localization of dark GRBs, robust estimates of the extinction in the absence of any optical/near-IR detections, and a comparative study of their explosion properties and parsec-scale environments.

The plan of the paper is as follows. We describe the multi-wavelength observations of GRBs 110709B and 111215A and their host galaxies in Section 2. These observations establish that both events are dark due to extinction. We model the radio and X-ray data to extract the minimum required extinction, as well as the explosion and circumburst properties in Section 3. In Section 4 we place the large inferred extinction values and the inferred burst properties within the framework of existing samples of optically-bright and dark bursts. We summarize the results and note key future directions in Section 5. Throughout the paper we report magnitudes in the AB system (unless otherwise noted) and use Galactic extinction values of $E(B-V) \approx 0.044$ mag for GRB 110709B and $E(B-V) \approx 0.057$ mag for GRB 111215A (Schlafly & Finkbeiner 2011). We use the standard cosmological parameters: $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_\Lambda = 0.73$, and $\Omega_M = 0.27$.

2. OBSERVATIONS

2.1. Discovery and Burst Properties

2.1.1. GRB 110709B

GRB 110709B was discovered on 2011 July 9 at 21:32:39 UT (Cummings et al. 2011b) by the Swift Burst Alert Telescope (BAT; 15–150 keV; Barthelmy et al. 2005), and by Konus-WIND (20 keV–5 MeV; Golenetskii et al. 2011). Swift X-ray Telescope (XRT; 0.3–10 keV; Burrows et al. 2005) observations commenced at $\delta t \approx 80$ s (Cummings et al. 2011b), localizing the X-ray afterglow to R.A. = $10^h58^m37^s08$, decl. = $-23^\circ27'17''6$ (J2000), with an uncertainty of 1″4 (90% containment, UVOT-enhanced; Beardmore et al. 2011a). Swift UV/Optical Telescope (UVOT; Roming et al. 2005) observations began at $\delta t \approx 90$ s, but no afterglow candidate was identified in 3107 s to a 3σ limit of 23.0 mag in the white filter (Oates 2011; Oates et al. 2012). The duration and fluence are $T_{90} \approx 796$ s and $F_\gamma = (4.5 \pm 0.5) \times 10^{-6}$ erg cm$^{-2}$ (15–150 keV; Barthelmy et al. 2011a).

2.2. X-Ray Observations

2.2.1. GRB 110709B

We analyzed the XRT data using the HEASOFT package (v6.11) and corresponding calibration files. We utilized standard filtering and screening criteria, and generated a count-rate light curve following the prescriptions by Margutti et al. (2010). The data were re-binned with the requirement of a minimum signal-to-noise ratio (S/N) of 4 in each temporal bin.

The XRT data exhibit significant spectral evolution during the early bright phase ($\delta t \lesssim 1$ ks), with spectral hardening when the burst re-brightened at about 11 minutes. Due to this variation, we performed a time-resolved spectral analysis, accumulating signal over time intervals defined to contain a minimum of about 1000 photons. Spectral fitting was done with xspec (v12.6; Arnaud 1996), assuming a photoelectrically absorbed power law model and a Galactic neutral hydrogen column density of $N_H = 5.6 \times 10^{20}$ cm$^{-2}$ (Kalberla et al. 2005). We extracted a spectrum in a time interval when no spectral evolution was apparent (15–150 ks) and used this to estimate the contribution of additional absorption. We find that the data are best modeled by an absorbed power-law\footnote{we define $\delta t$ as $\delta t = \delta t_{\text{B}} \times \delta t_{\text{UVOT}} \times \delta t_{\text{pow}}$:} model with a spectral photon index of $\Gamma = 2.3 \pm 0.1$ and excess absorption of $N_H = 1.4 \pm 0.2 \times 10^{21}$ cm$^{-2}$ at $z = 0$ (90% c.l., C-stat = 559 for 604 degrees of freedom). The excess absorption was used as a fixed parameter in the time-resolved spectral analysis, allowing us to derive a count-to-flux conversion factor for each spectrum. The resulting unabsorbed 0.3–10 keV flux light curve properly accounts for spectral evolution of the source. We note that for the purpose of display in Figure 1 we binned the XRT data by orbit at $\delta t \lesssim 2$ days and by multiple orbits thereafter.

We also observed GRB 110709B for 15 ks with the Advanced CCD Imaging Spectrometer (ACIS-S) on-board the Chandra X-ray Observatory on 2011 July 23.60 UT ($\delta t \approx 13.7$ days). The afterglow is detected with a count rate of $(4.1 \pm 0.5) \times 10^{-3}$ s$^{-1}$ (0.5–8 keV), corresponding to an unabsorbed 0.3–10 keV flux of $(6.0 \pm 0.7) \times 10^{-14}$ erg s$^{-1}$ cm$^{-2}$ using the XRT spectral parameters. Relative astrometry with the Chandra position will be discussed in Section 2.6. A second, 9 ks Chandra/ACIS-S observation was performed on 2011 October 31.83 UT ($\delta t \approx 113.4$ days). The X-ray afterglow is not detected to a 3σ limit of $\lesssim 9 \times 10^{-15}$ erg s$^{-1}$ cm$^{-2}$, well above the extrapolation of the early light curve to this epoch (Figure 1).

At $\delta t \gtrsim 12$ days the XRT light curve flattens to a level of about $10^{-13}$ erg s$^{-1}$ cm$^{-2}$. The Chandra observations reveal that this is due to a contaminating source located about 3′′8 from the GRB position, well within the point spread function (PSF) of XRT. We subtract the flux of this source, $(6.0 \pm 0.7) \times 10^{-14}$ erg s$^{-1}$ cm$^{-2}$, from the XRT light curve of GRB 110709B in Figure 1.\footnote{we note that the flux from the contaminating source is constant between the two epochs of Chandra, and rules out any origin as a lensed counterpart of the GRB, which may have caused the two $\gamma$-ray triggers.}

2.2.2. GRB 111215A

We analyzed the XRT data for GRB 111215A in the same manner described above. At $\delta t \lesssim 2$ ks the light curve exhibits...
flares with a hard-to-soft spectral evolution. To obtain a reliable estimate of the intrinsic neutral hydrogen absorption in addition to the Galactic value ($N_{\text{H, MW}} = 5.5 \times 10^{20}$ cm$^{-2}$; Kalberla et al. 2005), we extracted a spectrum collecting the photon count data in the time interval 5–2000 ks, when no spectral evolution is apparent. The data are best-modeled by an absorbed power-law with $\Gamma = 2.2 \pm 0.1$ and $N_{\text{H, lim}} = (3.1 \pm 0.4) \times 10^{21}$ cm$^{-2}$ at $z = 0$ (90% c.l., C-stat = 499.13 for 512 degrees of freedom). The resulting unabsorbed 0.3–10 keV flux light curve is shown in Figure 2.

### 2.3. Optical/Near-IR Afterglow Limits

#### 2.3.1. GRB 110709B

We observed GRB 110709B with the Gemini Multi-Object Spectrograph (GMOS; Hook et al. 2004) on the Gemini-South 8 m telescope in r-band on 2011 July 10.03 and 13.96 UT ($\delta t \approx 3.2$ hr and 4.1 days). We analyzed the data with the gemini package in IRAF, but did not detect any sources within the XRT error circle to 3σ upper limits of $F_{\nu, \text{lim}} = (3.1 \pm 0.4) \times 10^{21}$ cm$^{-2}$ at $z = 0$ (90% c.l., C-stat = 499.13 for 512 degrees of freedom). The derived parameters are listed in Table 1.

#### 2.3.2. GRB 111215A

Several optical afterglow searches on timescales of $\delta t \approx 7$ minutes to 6.8 hours led to non-detections of an afterglow with limits of $\geq 17.5 – 22.8$ mag in various filters (e.g., Xin 2011; Xu et al. 2011; Usui et al. 2011; Pandey et al. 2011; Gorbovskoy et al. 2011; Rumyantsev et al. 2011). We observed the position of GRB 111215A with the Observatorio de Sierra Nevada (OSN) 1.5 m telescope beginning 2011 December 15.75 UT ($\delta t \sim 4$ hr) and obtained a deep r-band limit of $m_r \approx 21.7$ mag. The deepest optical limit is $m_K \approx 22.8$ mag at a mid-time of $\delta t \approx 37$ minutes (Xu et al. 2011), corresponding to a flux density of $F_{\nu, \text{opt}} \lesssim 2.3$ μJy. Near-IR observations also led to non-detections (D’Avanzo et al. 2011; Tanvir et al. 2011), with the deepest limit being $m_K \approx 19.3$ mag (Vega) at $\delta t \approx 0.2$ days (Tanvir et al. 2011), corresponding to $F_{\nu, \text{NIR}} \lesssim 12$ μJy.

A comparison of the deepest optical limit to the X-ray flux density at the same time ($F_{\nu, X} \approx 54$ μJy) indicates $\beta_{\text{OX}} \lesssim -0.5$. Similarly, a comparison of the deepest near-IR limit to the X-ray flux density at the same time ($F_{\nu, X} \approx 4.2$ μJy) indicates...
β_{NIRX} \lesssim 0.15. In comparison to the X-ray spectral index we find \( β_{OX} - β_X \lesssim -1.7 \) and \( β_{NIRX} - β_X \lesssim -1.05. Thus, GRB 111215A is a dark burst in the optical and near-IR. As in the case of GRB 110709B, the absence of optical/near-IR emission can be due to dust extinction, or alternatively to a high redshift, \( z \gtrsim 18 \) based on the \( K_s \)-band non-detection.

### 2.4. JVLA Centimeter Observations
#### 2.4.1. GRB 110709B

We observed GRB 110709B with the NRAO Karl G. Jansky Array (JVLA) beginning on 2011 July 11.97 UT (\( δt \approx 2.1 \) days) at a mean frequency of 5.8 GHz and detected a single, unresolved radio source within the XRT error circle. This detection provided the first accurate position for the burst. Follow-up observations demonstrated that the source initially brightened and subsequently faded away, establishing it as the radio afterglow of GRB 110709B.

All observations utilized the WIDAR correlator (Perley et al. 2011b) with \( \sim 2 \) GHz bandwidth. We calibrated and analyzed the data using standard procedures in the Astronomical Image Processing System (AIPS; Greisen 2003). We excised edge channels and channels affected by radio frequency interference, reducing the effective bandwidth by \( \sim 25\% \) at 5.8 GHz. Due to the low declination of the source, we also excised data when \( >2 \) m of a given antenna was shadowed by another antenna. For the observation at 21.8 GHz, we performed reference pointing at 8.4 GHz and applied the pointing solutions, per standard high frequency observing procedures. We observed 3C286 for band-pass and flux calibration and interleaved observations of J1048–1909 for gain calibration every 3 m at 21.8 GHz and J1112–2158 every 4 m at 5.8 GHz. The resulting flux densities at 5.8 and 21.8 GHz are listed in Table 2. The uncertainties are \( 1\sigma \) statistical errors, and we note an additional uncertainty in the absolute flux scaling of \( \sim 5\% \). The 5.8 GHz light curve is shown in Figure 1.

Finally, to determine the position of the radio afterglow we fit the source in each image with a Gaussian profile (AIPS task JMFIT), and calculated the mean radio position weighted by the resulting statistical uncertainties. We find a weighted mean position of R.A. = 10°58′37.113 (+0.001), decl. = -23°27′16″.76 (+0.02).

#### 2.4.2. GRB 111215A

We observed GRB 111215A with the JVLA beginning on 2011 December 17.00 UT (\( δt \approx 1.4 \) days), and subsequently detected the radio afterglow starting at \( δt \approx 3.35 \) days. Observations between 1.4 and 140 days were obtained at mean frequencies of 5.8, 8.4, and 21.8 GHz. We used 3C48 for band-pass and flux calibration and interleaved observations of J2311+3425 every \( \sim 4 \) m for gain calibration at 21.8 GHz and J2340+2641 every \( \sim 5.5 \) m for gain calibration at 5.8 and 8.4 GHz. The data were analyzed in the same manner described above, and the resulting flux densities are listed in Table 3. The light curves are shown in Figures 2 and 3.

We obtain a weighted mean position from all 21.8 GHz detections of R.A. = 23°18′13″.314 (+0.004), decl. = +32°29′39″.07 (+0.06). The JVLA data (along with CARMA observations: Section 2.5) provide the only sub-arcsecond position for GRB 111215A.

#### 2.5. Millimeter Observations
##### 2.5.1. GRB 110709B

GRB 110709B was observed at a frequency of 345 GHz with the Large APEX Bolometer Camera (LABOCA; Siringo et al. 2009) on the Atacama Pathfinder Experiment (APEX) telescope beginning on 2011 July 11.90 UT (\( δt \approx 2.0 \) days). No submillimeter counterpart was detected to a 3\( σ \) upper limit of \( \lesssim 6.9 \) mJy (de Ugarte Postigo et al. 2011).

##### 2.5.2. GRB 111215A

We observed and detected GRB 111215A with the Combined Array for Research in Millimeter Astronomy (CARMA) beginning on 2011 December 16.97 UT (\( δt \approx 1.38 \) days) at 93 GHz and we continued monitoring the afterglow at this frequency for \( \approx 16 \) days; see Table 3. We used Neptune as the primary flux calibrator, and 3C454.3 as our band-pass calibrator, and 2236+284 and 2203+317 as gain calibrators. The overall uncertainty in

* Results from stacking all three epochs.
We also observed GRB 111215A with the IRAM Plateau de Bure interferometer (PdBI) on 2011 December 26.67 (Δt ≈ 11.1 days) at 94.5 GHz under excellent weather conditions in dual polarization with the 3.6 GHz bandwidth of the WIDEX correlator, detecting the afterglow at a flux level (1380 ± 60 μJy) consistent with our CARMA observations. We utilized MWC349, 3C454.3, and J2253+326 for flux, band-pass and gain calibration, respectively. We continued observations with PdBI over the course of two months until the source faded below the detection threshold. In the first two epochs of observations when the source was very bright (S/N ≈ 20), we checked for flux variability. We report no evidence for significant flaring (as found in another dark burst, GRB 051022; Castro-Tirado et al. 2007): the flux was constant within 1.5σ errors. We calibrated and verified the data with the MIRIAD software package (Sault et al. 1995), and measured the flux densities with AIPS for consistency with the JVLA observations (Table 3). We fit the position of the detected mm afterglow in each epoch with a Gaussian fixed to the beam size, and compute the mean position, weighted by the uncertainty in each epoch, leading to R.A. = 23°18′13″321 ± (±0.007) and decl. = +32°29′39″04 ± (±0.07). This position is consistent with the Swift/X-ray position.

The overall uncertainty in flux calibration for PdBI is ~10%–20%. The CARMA and PdBI observations utilized different gain calibrators, but both had observations of 3C454.3 for band-pass calibration, giving us confidence in the relative flux scaling (4.3 Jy at CARMA on December 26.01 at 93 GHz and 4.39 Jy at PdBI on December 26.67 at 94.5 GHz). The millimeter data are summarized in Table 3 and the first panel of Figure 3.

We observed GRB 111215A with the Submillimeter Array (SMA; Ho et al. 2004) beginning on 2011 December 18.15 UT (Δt = 2.7 days) at 230 GHz with 8 GHz bandwidth. We performed gain calibration using J2311 + 344 and J2236+284, band-pass calibration using 3C84, and flux calibration using real-time measurements of the system temperatures, with observations of Uranus and Callisto to set the overall flux scale (accurate to about 10%). We calibrated the data using the MIRIAD software package (Sault et al. 1995), and measured the flux densities with AIPS for consistency with the JVLA observations (Table 3). We fit the position of the detected mm afterglow in each epoch with a Gaussian fixed to the beam size, and compute the mean position, weighted by the uncertainty in each epoch, leading to R.A. = 23°18′13″321 ± (±0.007) and decl. = +32°29′39″04 ± (±0.07). This position is consistent with the Swift/X-ray position.

the absolute flux calibration is ~20%. We calibrated and visualized the data with the MIRIAD software package (Sault et al. 1995), and measured the flux densities with AIPS for consistency with the JVLA observations (Table 3). We fit the position of the detected mm afterglow in each epoch with a Gaussian fixed to the beam size, and compute the mean position, weighted by the uncertainty in each epoch, leading to R.A. = 23°18′13″321 ± (±0.007) and decl. = +32°29′39″04 ± (±0.07). Figure 3. Radio light curves of GRB 111215A at 5.8, 8.4, 19.1, 24.4, and 87–95 GHz. Afterglow model fits are shown with the solid lines. The derived afterglow parameters are listed in Table 5.

(A color version of this figure is available in the online journal.)
software package, and analyzed and imaged the observation with MIRIAD. We do not detect the GRB afterglow to a 3σ limit of $\lesssim 2.6$ mJy.

2.6. Host Galaxy Observations and Redshift Constraints

2.6.1. GRB 110709B

We obtained Hubble Space Telescope (HST) observations of GRB 110709B with the Wide Field Camera 3 (WFC3; Kimble et al. 2008) on 2011 November 8.94 UT ($\delta t \approx 122$ days) using the ultraviolet imaging spectrograph (UVIS) with the F606W filter, and on 2011 November 12.94 UT ($\delta t \approx 126$ days) using the infrared (IR) channel with the F160W filter (PI: Levan). One orbit of observations was obtained in each filter, with exposure times of 2610 s (F606W) and 2480 s (F160W). The data were processed using multidrizzle (Fruchter & Hook 2002; Koekemoer et al. 2002) with output pixel scales set at $0.02$ and $0.07$, respectively.

To locate the absolute radio and X-ray afterglow positions on the HST images we tie the F606W and F160W images to the 2MASS reference frame using a wider field Gemini-South GMOS r-band image as an intermediary. Using 20 common sources with 2MASS, the absolute astrometry of the Gemini image has an rms scatter of $\sigma_{\text{GMOS-2MASS}} = 0.15$ in each coordinate. The HST images are tied to the GMOS image using 30 common sources with a resulting rms scatter of $\sigma_{\text{HST-GMOS}} = 0.03$ in each coordinate. We further refine the Chandra afterglow position relative to the HST astrometric frame using a single common source. This leads to a shift in the X-ray position of $\delta$R.A. = $-0.10$ ($-0.07$) and $\delta$decl. = $+0.20$ (+0.18) relative to the F606W (F160W) reference frame. There are no common sources between the HST and JVLA images.

The resulting uncertainty in the radio afterglow position in the HST reference frame is dominated by the absolute astrometry, and corresponds to a radius of $0.22$ ($1\sigma$; the centroid uncertainty of the radio position is only $0.02$ in each coordinate). The uncertainty in the X-ray afterglow position is reduced by the relative tie of the Chandra and HST reference frames, leading to a radius of $0.10$ ($1\sigma$; the centroid uncertainty of the Chandra position is about $0.08$ in each coordinate). Within the uncertainty regions we find a single galaxy in both HST images (Figure 4), which we identify as the host of GRB 110709B. Photometry of this source using the tabulated WFC3 zero points gives $m_{\text{F606W}} = 26.78 \pm 0.17$ AB mag and $m_{\text{F160W}} = 25.13 \pm 0.10$ mag, corrected for Galactic extinction.

To determine the probability of chance coincidence, $P_{cc}(\angle R) = 1 - \exp[-\pi(\delta R)^2 \sigma(\angle m)]$, we use the galaxy number counts, $\sigma(\angle m) = 10^{0.25(m-25)} - 1.2$ arcsec$^{-2}$ (Hogg et al. 1997; Beckwith et al. 2006). For the XRT error circle we infer $P_{cc} \approx 0.1$, while for the more precise JVLA and Chandra positions we find $P_{cc} \approx 0.006$ and $0.001$, respectively. Thus, the sub-arcsecond radio and X-ray positions enable a robust association with the galaxy, while the XRT position alone would have led to marginal confidence. This is essential since the detection of the host galaxy in the F606W filter limits the redshift to $z \lesssim 4$, indicating that GRB 110709B is dark due to extinction and not a z $\gtrsim 18$ origin.

For a redshift from $z \sim 1$, the F606W band samples the rest-frame UV emission from the host galaxy. Based on the observed flux density calculated from the apparent magnitude ($m_{\text{F606W}} = 26.78 \pm 0.17$ AB mag) assuming the standard cosmological parameters noted in Section 1 to calculate the luminosity distance (Wright 2006), we utilize Equation (1) in Kennicutt (1998)

$$\text{SFR} (M_\odot \text{yr}^{-1}) = 1.4 \times 10^{-28} L_\nu \text{ (erg s}^{-1}\text{Hz}^{-1})$$

(1)

to infer SFR $\approx 0.3-3.2 M_\odot \text{yr}^{-1}$ for $z = 1-4$, not corrected for possible galactic-scale extinction.

2.6.2. GRB 111215A

We obtained i-band observations of GRB 111215A with GMOS on the Gemini-North 8 m telescope on 2011 December 23.21 UT ($\delta t \approx 7.6$ days), with a total exposure time of 2160 s in $0.9$ seeing. Astrometric matching to the 2MASS catalog using 30 common sources reveals a galaxy within the enhanced XRT error circle at R.A. = $23^h18^m13.3^s$, decl. = $+32^\circ29^\prime38.7^\prime$, with an uncertainty of about $0.16$ in each coordinate (absolute) and an uncertainty of about $0.06$ in the galaxy centroid; see Figure 5. We obtained imaging observations with the Low-Resolution Imaging Spectrometer (LRIS; Oke et al. 1995) on the Keck I 10 m telescope on 2012 July 15.20 UT ($\delta t = 212.6$ days) in the g- and i-band filters. Finally, we also obtained observations of the GRB 111215A host galaxy with the OSIRIS instrument (Sánchez et al. 2012) on the 10.4 m Gran Telescopio Canarias (GTC) on 2012 August 23.02 UT in the griz bands with an average seeing of $0.9$.
Taking into account the uncertainty in the JVLA radio afterglow position (0′.06 in each coordinate), the resulting overall uncertainty in the location of the afterglow on the Gemini image is 0′.26 radius (1σ). Similarly, the uncertainty in the CARMA mm afterglow position (0′.08 in each coordinate) leads to an overall uncertainty of 0′.27 radius (1σ). The resulting offset between the host centroid and radio positions is 0′.30 ± 0′.26.

Photometry of the galaxy relative to the Sloan Digital Sky Survey catalog results in a brightness of $m_g = 24.40 \pm 0.18$, $m_r = 24.24 \pm 0.15$, $m_i = 23.87 \pm 0.18$, and $m_z = 23.90 \pm 0.36$ (GTC), and $m_g = 24.50 \pm 0.15$ mag and $m_r = 23.64 \pm 0.05$ mag corrected for Galactic extinction (Gemini). The probability of chance coincidence for this galaxy within the XRT error circle is $P_c \approx 0.01$, with a slightly lower probability of $\approx 7 \times 10^{-3}$ using the radio position, dominated by the physical extent of the galaxy of about 1″.

The low chance coincidence probability we consider this galaxy to be the host of GRB 111215A.

To determine the redshift of the host we obtained an 1800 s spectrum with the Low Resolution Imaging Spectrometer (LRIS; Oke et al. 1995; Rockosi et al. 2010) on Keck I using a 0.7 slit with the 400/3400 grism in the blue arm and the 400/8500 grating in the red arm, providing effectively continuous wavelength coverage from the atmospheric cutoff to 10280 Å (with a total throughput within 50% of peak to about 10030 Å). The slit was oriented to cover the host galaxy, as well as the fainter extended source to the northeast. The spectrum was reduced using standard techniques implemented in a custom pipeline.

We detect continuum emission from both galaxies on the blue side, and from the host galaxy on the red side. We identify only one emission feature from the nearby galaxy, a marginally resolved line centered at 8019 Å. Interpreted as the $[\text{O} \text{II} \lambda \lambda 3727$ doublet, this indicates a redshift $z = 1.152$. We do not identify any emission lines from the host galaxy. Given that the galaxy is reasonably bright in $g$- and $i$-band and is expected to be actively star-forming, the lack of emission lines indicates that $z \gtrsim 1.8$ (from the non-detection of $[\text{O} \text{II} \lambda \lambda 3727$ to 10030 Å) and $z \lesssim 2.9$ (from the absence of a break due to the Lyman limit to 3860 Å).21

At $z \sim 1.8–2.9$, the observed $i$- and $g$-band fluxes trace the host galaxy rest-frame UV emission. The observed color of $g - i \approx 0.85 \pm 0.20$ mag is indicative of extinction; for example, it is well-matched to the observed color of Arp 220, a local ULIRG. Using the observed $i$-band flux density, which is less susceptible to extinction corrections, we infer SFR $\approx 15–30 \ M_\odot \ yr^{-1} (z = 1.8–2.9)$, which should be considered as a minimum value due to the uncertain extinction.

3. AFTERGLOW MODELING AND REST-FRAME EXTINCTION

GRBs 110709B and 111215A are dark in both the optical and near-IR bands due to rest-frame dust extinction; a high-redshift origin is ruled out by the association with optically-detected host galaxies. It is also of note that for extreme redshifts ($z > 18$), the $N_{\text{H, \text{int}}}$ implied by the observed excess in the X-ray spectra would be very high (e.g., $>10^{24}$ cm$^{-2}$), further supporting the rejection of an extreme redshift for either event. In addition to providing accurate localizations and hence secure host associations, the radio data also allow us to determine the properties of the bursts and their local environments. This not only provides a more robust measure of the required rest-frame extinction than using $\beta_{\text{ox}}$ alone (which requires an assumption about the location of the synchrotron cooling frequency), but it also allows us to compare the explosion properties of dark and optically-bright bursts.

We model the radio and X-ray data for GRBs 110709B and 111215A using the standard afterglow synchrotron model (Granot & Sari 2002; Sari et al. 1999) to (1) determine the expected optical and near-IR brightness, and hence the required level of rest-frame extinction given the observed limits; and (2) determine the properties of the bursts and their circumburst environments. We follow the standard assumptions of synchrotron emission from a power-law distribution of electrons ($N(\gamma) \propto \gamma^{-p}$ for $\gamma \gtrsim \gamma_m$) with constant fractions of the post-shock energy density imparted to the electrons ($\epsilon_e$) and magnetic fields ($\epsilon_B$). The additional free parameters of the model are the isotropic-equivalent blast-wave kinetic energy ($E_{K, \text{iso}}$), the circumburst density (parameterized as $n$ for a constant density medium: ISM; or as $A$ for a wind medium with $\rho(r) = A/r^2$), and a jet break time ($t_j$). To determine the opening angle ($\theta_j$), we use the conversions from $t_j$, given by Sari et al. (1999) and Chevalier & Li (2000), with the appropriate dependence on $E_{K, \text{iso}}$ and the circumburst density ($n$ or $A$, respectively).

Using the time evolution of the synchrotron spectrum for both the interstellar medium (ISM) and wind density profiles in the pre- and post-jet break phases (Chevalier & Li 2000; Granot & Sari 2002) we simultaneously fit all X-ray and radio observations for each burst. The resulting best-fit parameters are summarized in Tables 4 and 5 using redshifts of $z = 1, 2, 3, 4$ for GRB 110709B and $z = 2$ for GRB 111215A. In both cases we find that the most stringent constraint on the rest-frame extinction are provided by the observed $K$-band limits. We use the Small Magellanic Cloud (SMC) extinction curve to

\[ \text{Figure 5.} \text{Gemini/GMOS } i\text{-band image of the host galaxy of GRB 111215A.} \text{ The XRT error circle (1′.4 radius; 90% containment) is indicated with the black circle. The JVLA and CARMA afterglow positions are shown with a blue circle (0′.13; 1σ systematic) coinciding with a galaxy that we consider to be the host of GRB 111215A.} \]
determine the rest-frame extinction, although the Milky Way extinction curve gives similar results.

For GRB 110709B we find that the data favor a wind environment, with a jet break at \( t_j \approx 3.1–3.6 \) days, corresponding to an opening angle, \( \theta_j \approx 9°–23° \); the jet break occurs earlier and the resulting opening angle is narrower as the redshift increases from \( z = 1 \) to \( z = 4 \). The resulting beaming-corrected energies are \( E_K \approx (0.4–1.7) \times 10^{51} \text{ erg} \) and \( E_V \approx (5.4–10.6) \times 10^{51} \text{ erg} \) (in the observed 20–5000 keV fluence of the initial event). The circumburst density is characterized by a mass-loss rate of \( M \approx (4–8) \times 10^{-5} M_{\odot} \text{ yr}^{-1} \) for a wind velocity of \( v_w = 10^5 \text{ km s}^{-1} \) (i.e., \( A^* \approx 4–8 \)). Finally, using the near-IR \( K_s \)-band limit we find that the required extinction ranges from \( A_V^{\text{host}} \gtrsim 10.5 \text{ mag} \) at \( z = 1 \) to \( \gtrsim 5.5 \text{ mag} \) at \( z = 4 \). We note that the best-fit ISM model also requires a high density of \( \sim 10–100 \text{ cm}^{-3} \) at \( z \approx 1–4 \).

For GRB 111215A we again find that a wind environment provides a better fit, with a jet break at \( t_j \approx 12 \) days, corresponding to an opening angle of \( \theta_j \approx 24° \). The resulting beaming-corrected energies are \( E_K \approx 3.7 \times 10^{51} \text{ erg} \) and \( E_V \approx 3.9 \times 10^{51} \text{ erg} \) (in the observed 15–150 keV band).

The circumburst density is characterized by a substantial mass-loss rate of \( M \approx 2 \times 10^{-4} M_{\odot} \text{ yr}^{-1} \) (for a wind velocity of \( v_w = 10^5 \text{ km s}^{-1} \)). Finally, using the near-IR \( K_s \)-band limit we find a required extinction of \( A_V^{\text{host}} \gtrsim 8.5 \text{ mag} \) (for \( z = 2 \)). We note that the best-fit ISM model also requires a density of \( \sim 100–300 \text{ cm}^{-3} \). Dust extinction large is indicative of dust associated with the local environment of the GRB (e.g., Reichart & Price 2002; Campana et al. 2006).

### 4. DISCUSSION

#### 4.1. Extinction and Neutral Hydrogen Column Density

The large rest-frame extinction that is required to explain the lack of optical and near-IR emission from GRBs 110709B and 111215A is uncommon amongst known GRBs. In Figure 6 we plot the minimum values of \( A_V^{\text{host}} \) for the two bursts as a function of redshift, along with several comparison samples from the literature of optically-bright bursts and previous dark bursts. In general, optically-bright GRBs have inferred extinction values of \( \lesssim 1 \text{ mag} \), with a mean of \( \sim 0.2–0.3 \text{ mag} \) (Kann et al. 2006, 2010; Schady et al. 2007; Perley et al. 2009; Krühler et al. 2011). Dark GRBs span \( A_V^{\text{host}} \approx 1–6 \text{ mag} \) (Perley et al. 2009; Krühler et al. 2011; Prochaska et al. 2009; Castro-Tirado et al. 2007; Rol et al. 2007), with the largest extinction values of \( \lesssim 5–6 \text{ mag} \) inferred for GRBs 061222, 070306, and 070521 (Perley et al. 2009; Krühler et al. 2011; Jaunsen et al. 2008). In this context, the extinction values measured here are at the top of the distribution, \( A_V^{\text{host}} \gtrsim 5.3 \text{ mag} (110709B) \) and \( \gtrsim 8.5 \text{ mag} \) (111215A) at \( z = 2 \).

In Figure 7 we plot the intrinsic neutral hydrogen column densities, \( N_{H, \text{int}} \), from our X-ray analysis as a function of redshift, in comparison with the population of all Swift long GRBs with known redshifts (up to 2010 December; Margutti et al. 2013; see also Jakobsson et al. 2006 and Fynbo et al. 2009). We find that GRBs 110709B and 111215A lie at the upper end of the distribution for long GRBs. In particular, at a fiducial redshift of \( z = 2 \) they have \( \log(N_{H, \text{int}}) \approx 22.1 \) and \( \approx 22.5 \), respectively, in comparison with the median value of all detections and upper limits of \( \log(N_{H, \text{int}}) \approx 21.7 \). This result confirms recent suggestions that dark GRBs have systematically larger neutral...
hydrogen columns, generally with log \(N_{H,\text{int}} \gtrsim 22\) (Perley et al. 2009; Campana et al. 2012); see Figure 7. In their spectroscopic sample of GRBs, Fynbo et al. (2009) also find dark bursts to have higher excess absorption in general, and more specifically, the three bursts with highest column densities are dark. Indeed, only a handful of events in the Swift sample have values of \(N_{H,\text{int}}\) comparable to that of GRB 111215A (if \(z \gtrsim 2\)). The same conclusion is true for GRB 110709B if it resides at the upper end of the allowed redshift distribution (\(z \approx 3–4\)), although at \(z \sim 1\) its neutral hydrogen column is typical of the overall long GRB population.

A correlation between extinction and \(N_H\) is known to exist in the Milky Way and the Magellanic Clouds, with \(N_H \approx 2 \times 10^{21} \, \text{cm}^{-2}\) (Predehl & Schmitt 1995; Güver & Özel 2009; Watson 2011). As shown in Figure 8, optically-bright GRBs generally have lower values of \(A_V^{\text{host}}\) than would be inferred from this relation (e.g., Galama & Wijers 2001; Stratta et al. 2004; Zafar et al. 2011), with mean values of \(N_{H,\text{int}} \approx 5 \times 10^{21} \, \text{cm}^{-2}\) and \(A_V^{\text{host}} \approx 0.2–0.3 \, \text{mag}\); the expected extinction based on the Galactic relation is \(A_V^{\text{host}} \approx 2.5 \, \text{mag}\). Dark GRBs also generally have lower extinction than expected, with \(N_{H,\text{int}} \approx (5–50) \times 10^{21} \, \text{cm}^{-2}\) and \(A_V^{\text{host}} \approx 1–5 \, \text{mag}\), whereas extinctions of \(A_V^{\text{host}} \approx 5–25 \, \text{mag}\) would be expected.

For the bursts presented here we find potentially different results. GRB 111215A agrees with the Galactic relation if it resides at the lower redshift bound (\(z \approx 1.8\)), in which case \(N_{H,\text{int}} \approx 2.5 \times 10^{22} \, \text{cm}^{-2}\) and \(A_V^{\text{host}} \gtrsim 11 \, \text{mag}\). At the higher redshift bound (\(z \approx 2.7\)) we find \(N_{H,\text{int}} \approx 5 \times 10^{22} \, \text{cm}^{-2}\) and \(A_V^{\text{host}} \gtrsim 6 \, \text{mag}\) (with an expected \(A_V \approx 23 \, \text{mag}\)). This is still consistent with the Galactic relation since we only place a lower bound on \(A_V^{\text{host}}\). Similarly, GRB 110709B crosses the Galactic relation at \(z \approx 2\), with \(N_{H,\text{int}} \approx 1.2 \times 10^{23} \, \text{cm}^{-2}\) and \(A_V^{\text{host}} \gtrsim 5.3 \, \text{mag}\). However, at \(z \lesssim 2\) it has larger extinction than expected; for example, at \(z = 1\) we measure \(A_V^{\text{host}} \gtrsim 10.5 \, \text{mag}\) compared with the expected value of \(\approx 2.5 \, \text{mag}\). At \(z \gtrsim 2\) the situation is similar to GRB 111215A, namely the minimum value of \(A_V^{\text{host}}\) is below the expected Galactic relation, but this is only a lower limit. We therefore conclude that the dark bursts with the largest known extinction values are potentially in line with the Galactic \(N_H–A_V\) relation, although they may also reside below the expected correlation in line with the bulk of the GRB population.

4.2. Explosion and Circumburst Properties of Dark Bursts

A few previous dark GRBs have been localized to sub-arcsecond precision in the radio. GRB 970828 was detected in a single radio observation with \(F_r(8.46 \, \text{GHz}) = 147 \pm 33 \, \mu\text{Jy}\) (4.5\sigma), but was not detected in observations only 1 day earlier and 2 days later (Djorgovski et al. 2001). This single marginal detection was used to refine the position from the X-ray region of 10′′ radius, and to claim an association with a galaxy at \(z = 0.958\). The inferred extinction at this redshift is \(A_V^{\text{host}} \approx 3.8 \, \text{mag}\). GRB 060210 was localized to sub-arcsecond precision with Chandra, and was also marginally detected in the single epoch in the radio with \(F_r(8.46 \, \text{GHz}) = 93 \pm 21 \, \mu\text{Jy}\) (4.4\sigma; Piro et al. 2002). The associated host galaxy has \(z = 0.846\), and the inferred extinction is \(A_V^{\text{host}} \approx 0.9–3.2 \, \text{mag}\). GRB 020819 was detected at high significance in several epochs of radio observations, leading to an association with a face-on spiral galaxy at \(z = 0.410\) (Jakobsson et al. 2005). The required extinction was a mild \(A_V^{\text{host}} \approx 0.6–1.5 \, \text{mag}\). Finally, GRB 051022 was localized using radio and millimeter observations to a host galaxy at \(z = 0.809\), requiring an extinction of \(A_V^{\text{host}} \gtrsim 3.5 \, \text{mag}\) (Castro-Tirado et al. 2007; Rol et al. 2007). Broadband modeling indicates a beam-corrected energy of \(\approx 10^{51} \, \text{erg}\), and a circumburst density characterized by \(M \approx 3 \times 10^{-7} \, \text{M}_{\odot} \, \text{yr}^{-1}\) (Rol et al. 2007).

The beam-corrected energy inferred for GRBs 110709B and 111215A, \(E_V + E_K \approx (7–9) \times 10^{51} \, \text{erg}\), is not unusual for long GRBs, although it is somewhat higher than the median value of \(\approx 3 \times 10^{51} \, \text{erg}\) (e.g., Pian et al. 2002; Berger et al. 2003b; Cenko et al. 2011). On the other hand, the inferred densities are substantial, with inferred mass-loss rates of about \(6 \times 10^{-5} \, \text{M}_{\odot} \, \text{yr}^{-1}\) (110709B) and \(2 \times 10^{-4} \, \text{M}_{\odot} \, \text{yr}^{-1}\) (111215A). At the radii appropriate for the jet break times of the two bursts,
The Astrophysical Journal, 767:161 (13pp), 2013 April 20

The durations of GRB 110709B ($T_{90} \approx 850$ s) and GRB 111215A ($T_{90} \approx 800$ s) are extremely long. To assess whether this type of unusually long duration correlates with optical/near-IR darkness, we collect all Swift bursts with durations of $\gtrsim 500$ s, excluding nearby sub-energetic GRBs (e.g., XRF 060218, GRB 100316D) and GRBs without robust X-ray and optical follow-up observations. The sample includes nine events\(^{22}\), of which three bursts are dark (060929, 110709B, 111215A), five have optical and/or near-IR detections with no clear evidence for extinction, and one event lacks rapid follow-up observations. Thus, at least $\sim 1/3$ of these events are dark, similar to the fraction of dark bursts in the overall long GRB population. We therefore conclude that there is no obvious correlation between unusually long duration and darkness, with the caveat that the current sample size is small.

5. CONCLUSIONS

Using X-ray, optical/near-IR, and radio observations we have demonstrated that: (1) GRBs 110709B and 111215A are dark bursts; (2) they are robustly associated with galaxies at $z \lesssim 4$ (110709B) and $z \approx 1.8-2.9$ (111215A); (3) they require unusually large rest-frame extinction (among the highest $A_V \gtrsim 5.3$ mag (110709B) and $\gtrsim 8.5$ mag (111215A) at $z = 2$; (4) they exhibit commensurately large neutral hydrogen column densities in their X-ray spectra, $N_{H, \text{int}} \approx (1-3) \times 10^{22} \text{ cm}^{-2}$, which at $z \sim 2$ are consistent with the Galactic $N_H-A_V$ relation, unlike the overall long GRB population; and (5) their circumburst environments on a sub-parsec scale are shaped by large progenitor mass-loss rates of $\approx (6-20) \times 10^{-5} M_\odot \text{ yr}^{-1}$.

Radio observations played a critical role in this study for three reasons. First, they provided sub-arcsecond positions, which led to a secure identification of the host galaxies. This allowed us to distinguish the extinction scenario from a high-redshift origin. Second, the combination of radio and X-ray data allowed us to robustly determine the required extinction, instead of simply assuming an optical to X-ray spectral index. Indeed, in cases with only X-ray data the unknown location of the synchrotron cooling frequency prevents a unique determination of the extinction. Finally, the radio and X-ray data allowed us to determine the burst parameters, including the geometry, beaming-corrected energy, and the circumburst density. We find that the energy scale for GRBs 110709B and 111215A is similar to the overall population of optically-bright GRBs. However, the inferred mass-loss rates are larger by about an order magnitude compared with optically-bright bursts, potentially indicating that GRB progenitors in dusty environments have stronger metal line driven winds.

\(^{22}\) These are GRBs 041219A, 050820A, 060123, 060124, 060929, 091024, 110709B, 111016A, and 111215A.

The increased sensitivity of the JVLA played an important role in the study and utilization of the radio afterglow. ALMA will provide similar capabilities, with an expected spatial resolution of about $0\farcs04-0\farcs5$ at 100 GHz (depending on configuration), and hence an assured sub-arcsecond centroiding accuracy for S/Ns of $\gtrsim 10$ even in the most compact configuration. As demonstrated here, Chandra observations can also provide sub-arcsecond positions, but such observations may not be available for all dark GRB candidates (e.g., GRB 111215A). In addition, Chandra data will not enhance the ability to determine the required extinction through broadband modeling.

The JVLA and ALMA will also allow us to study the host galaxies of GRBs 110709B and 111215A (as well as those of past and future dark bursts) in greater detail than optical/near-IR studies alone. In particular, they will address the question of highly-obscured star formation in these galaxies, and may even lead to redshift determinations through the detection of molecular lines. Existing observations with the Very Large Array and the MAMBO and SCUBA bolometers (in the small samples published to-date) have led to only a few detections of GRB hosts (Berger et al. 2003a), with no obvious preference for dark burst hosts (Barnard et al. 2003). However, the enhanced sensitivity of ALMA will allow for detections even with star formation rates of tens of $M_\odot \text{ yr}^{-1}$ at $z \sim 2$. The combination of detailed host galaxy properties from rest-frame radio to UV, coupled with measurements of the local environments of dark bursts through broadband afterglow modeling will shed light on the location of the obscuring dust (interstellar versus circumstellar) and the impact of metallicity on GRB progenitor formation.

We thank R. Chary for helpful discussions regarding obscured star formation in distant galaxies and Y. Cao for his assistance in obtaining the optical spectrum of GRB 111215A while observing at Keck.
