\textbf{ABSTRACT}

\textbf{Context.} The disagreement between theoretical predictions and observations for surface lithium abundance in stars is a long-standing problem, which indicates that the adopted physical treatment is still lacking in some points. However, thanks to the recent improvements in both models and observations, it is interesting to analyse the situation to evaluate present uncertainties.

\textbf{Aims.} We present a consistent and quantitative analysis of the theoretical uncertainties affecting surface lithium abundance in the current generation of models.

\textbf{Methods.} By means of an up-to-date and well tested evolutionary code, FRANEC, theoretical errors on surface \textsuperscript{7}Li abundance predictions, during the pre-main sequence (pre-MS) and main sequence (MS) phases, are discussed in detail. Then, the predicted surface \textsuperscript{7}Li abundance was tested against observational data for five open clusters, namely Ic 2602, α Per, Blancol, Pleiades, and NGC 2516, and for four detached double-lined eclipsing binary systems. Stellar models for the aforementioned clusters were computed by adopting suitable chemical composition, age, and mixing length parameter for MS stars determined from the analysis of the colour–magnitude diagram of each cluster. We restricted our analysis to young clusters, to avoid additional uncertainty sources such as diffusion and/or radiative levitation efficiency.

\textbf{Results.} We confirm the disagreement, within present uncertainties, between theoretical predictions and \textsuperscript{7}Li observations for standard models. However, we notice that a satisfactory agreement with observations for \textsuperscript{7}Li abundance in both young open clusters and binary systems can be achieved if a lower convection efficiency is adopted during the pre-MS phase with respect to the MS one.

\textbf{Key words.} stars: abundances – stars: evolution – stars: interiors – stars: low-mass – stars: pre-main sequence – Hertzsprung-Russell and C-M diagrams

1. Introduction

In the past two decades, a large number of \textsuperscript{7}Li observations have been collected for isolated stars, binary systems, and open clusters from the pre-MS to the late MS phases (see e.g. Table 1 and references therein in Jeffries 2000; Sestito & Randich 2005), showing that \textsuperscript{7}Li depletion is a strong function of both mass and age. A detailed and homogeneous analysis has been carried out by Sestito & Randich (2005), who determined surface \textsuperscript{7}Li abundance for a large sample of open clusters in a wide range of ages and chemical compositions, supplying a useful tool for accurately analysing the temporal evolution of surface \textsuperscript{7}Li abundance.

Open clusters and detached double-lined eclipsing binaries (EBs) are ideal systems for testing the validity of stellar evolutionary models, since their members have the same chemical composition and age. As a consequence, they allow the different lithium depletion pattern to be investigated as a function of the stellar mass once the age and the chemical composition have been kept fixed.

Besides the large amount of \textsuperscript{7}Li data available, a strong effort in theoretical modelling has been made in the past years, and many different theoretical scenarios have been proposed to explain the observed surface \textsuperscript{7}Li abundance and its temporal evolution (see e.g. the reviews in Deliyannis et al. 2000; Pinsonneault et al. 2000; Charbonnel et al. 2000), both in the framework of standard and non-standard models (see e.g., Pinsonneault et al. 1990; Pinsonneault 1994; Chaboyer et al. 1995; D’Antona & Mazzitelli 1997; Ventura et al. 1998; Piau & Turck-Chièze 2002; D’Antona & Montalbán 2003; Montalbán & D’Antona 2006).

\textbf{Standard models} assume a spherically symmetric structure and convection and diffusion are the only processes that mix surface elements with the interior. Although the validity of such models in reproducing the main evolutionary parameters has been largely tested against observations, they fail to reproduce the observed \textsuperscript{7}Li abundances. Indeed, standard models show a \textsuperscript{7}Li depletion during the pre-MS phase that is much stronger than observed, while the opposite occurs in the MS phase (see e.g., Jeffries 2000). Moreover, they cannot fully account for the formation of the so-called lithium dip for MS stars in the temperature range 6000 K \(\lesssim T_{\text{eff}} \lesssim 7000\) K (Boesgaard & Tripicco 1986), see e.g. Richer & Michaud (1993).

The comparison between theory and observation is improved, in some cases, by introducing non-standard processes into the models, e.g. rotation, gravity waves, magnetic fields, and accretion/mass loss (Pinsonneault et al. 1990; D’Antona 1993; Chaboyer et al. 1995; Talon & Charbonnel 1998; Ventura et al. 1998; Mendes et al. 1999; Siess et al. 1999; D’Antona et al. 2000; Charbonnel & Talon 2005; Baraffe & Chabrier 2010; Vick et al. 2010). All these processes produce structural changes, with a related strong effect on lithium abundance (see e.g. the reviews by Charbonnel et al. 2000; Talon 2008; Talon & Charbonnel 2010). In particular, models with rotation-induced mixing plus...
gravity waves are able to reproduce $^7\text{Li}$ the depletion during the MS and post MS phases (i.e. the lithium dip feature and red-giant branch abundances, see e.g., Talon & Charbonnel 2010; Pace et al. 2012).

A crucial point in stellar modelling, both for standard and non-standard models, concerns the treatment of the over-adiabatic convection efficiency in the stellar envelope, which is an important issue for lithium depletion, too. In evolutionary codes, the most widely used convection treatment is the simplified scheme of the mixing length theory (MLT; Böhm-Vitense 1958). In this formalism, convection efficiency depends on a free parameter to be calibrated. It is a common approach to calibrate it by reproducing the solar radius. This choice usually gives good agreement between models and photometric data; however, to reproduce the effective temperature of stars with different masses in different evolutionary phases, an ad hoc value of the mixing length parameter should be adopted, as suggested by observations (see e.g., Chieffi et al. 1995; Morel et al. 2000; Ferraro et al. 2006; Yıldız 2007; Gennaro et al. 2012; Piau et al. 2011; Bonaca et al. 2012) and detailed hydrodynamical simulations (see e.g., Ludwig et al. 1999; Trampedach 2007).

The main goal of this paper is to re-examine the old lithium problem in light of the improvements in the adopted physical inputs and observational data and to perform a quantitative analysis of the uncertainties affecting surface lithium depletion during the pre-MS phase. The aim is to compute, by means of updated models, theoretical error bars to be applied to the comparison between predictions and data available for stars in young open clusters and binary systems, as partially done in earlier other works (see e.g., D’Antona & Mazzitelli 1984; Swenson et al. 1994; Ventura et al. 1998; Piau & Turck-Chièze 2002; Sestito et al. 2006).

The paper is structured in the following way. Section 2 presents the adopted $^7\text{Li}$ data sample for the selected open clusters, followed by a brief description of present models (Sect. 3). In Sect. 4 we evaluate the main theoretical uncertainties affecting surface lithium abundance. Finally, in Sect. 5, the comparison between predicted and observed lithium abundances for both young open clusters and binary systems is discussed.

2. Lithium data

Surface $^7\text{Li}$ abundances for young open clusters are taken from the homogeneous database made available by Sestito & Randich (2005). Here, we focus our analysis on clusters younger than about 150–200 Myr, in order to avoid MS depletion effects (see e.g., Sestito & Randich 2005), with different metallicities for which a significant number of data in a wide range of effective temperatures are available. The clusters that satisfy these criteria are, IC 2602, ω Per, Blanco 1, Pleiades, and NGC 2516.

Lithium abundances for young double-lined eclipsing binaries are not present in the database by Sestito & Randich (2005), but they have been measured by different authors, as we discuss in Sect. 5.2.

3. Theoretical stellar models

Present stellar models were computed with an updated version of the FRANEC evolutionary code (Degl’Innocenti et al. 2008), which adopts the most recent input physics, as described in detail by Tognelli et al. (2011). The initial deuterium mass fraction abundance is fixed to $X_D = 2 \times 10^{-5}$ as a representative value for population I stars (see e.g. Geiss & Gloeckler 1998; Linsky et al. 2006; Steigman et al. 2007). The logarithmic initial lithium abundance is assumed to be $\epsilon_{\text{Li}} = 3.2 \pm 0.2$ (see e.g., Jeffries 2006; Lodders et al. 2009), which approximatively corresponds to $X_{^7\text{Li}} \approx 7 \times 10^{-8} - 1 \times 10^{-8}$ in dependence on the metallicity adopted for the models\(^1\).

Convection is treated according to the mixing length theory, using the same formalism presented in Cox & Giuli (1968). The adopted reference value of mixing length parameter is $\alpha = 1.0$ (as suggested by present comparison with pre-MS data, see Sect. 5.1).

4. Theoretical uncertainties

4.1. Chemical composition

To properly calculate pre-MS evolution suitable initial abundances of helium, light elements, and metals are needed. For most of the stars, however, only the $[\text{Fe}/\text{H}]$ value is available, so theoretical or semi-empirical assumptions are required.

Assuming for Population I stars a solar-scaled heavy elements distribution (see e.g., Asplund et al. 2009, for a detailed review), the $X/Z$ value currently present at the stellar surface can be directly inferred from the observed $[\text{Fe}/\text{H}]$. For all the stars analysed in the paper, this value can be safely adopted as a good approximation of the initial one over the whole structure, since the effect of microscopic diffusion is negligible owing to the very young ages involved. The initial helium content of the star $Y$ cannot be directly measured in the stellar spectra of cool stars, so a further relation between the initial metallicity and helium of the star is required. A common way to proceed is to assume the following linear relation (see e.g., Gennaro et al. 2010):

$$Y = Y_\odot + \frac{\Delta Y}{\Delta Z}Z$$

where $Y_\odot$ and $\Delta Y/\Delta Z$ represent, respectively, the primordial helium abundance and the helium-to-metal enrichment ratio. For the calculations we adopt $Y_\odot = 0.2485 \pm 0.0008$ (Cyburt et al. 2004) and $\Delta Y/\Delta Z = 2 \pm 1$ (Casagrande et al. 2007). Thus, the metallicity of the star can be obtained directly from the following equation,

$$Z = \frac{(1 - Y_\odot)(Z/X)_\odot}{1 + [\text{Fe/H}]} - (1 + \Delta Y/\Delta Z)(Z/X)_\odot$$

once the solar $(Z/X)_\odot$ has been specified. Regarding this last quantity, there are several values adopted by different authors, i.e. the still widely adopted Grevesse & Noels (1993, GN93; $(Z/X)_\odot = 0.0244)$, Grevesse & Sauval (1998, GS98; $(Z/X)_\odot = 0.0231$) and the recent determinations by Asplund et al. (2005, AS05; $(Z/X)_\odot = 0.0165$) and Asplund et al. (2009, AS09; $(Z/X)_\odot = 0.0181$), which are based on detailed 3D hydrodynamical atmosphere models. Recently, Caffau et al. (2010, CL10) have found a value for the solar carbon photospheric abundance higher by about 0.1 dex than the previous one derived by AS09. This also leads to an increase in the solar metallicity-to-hydrogen ratio, namely $(Z/X)_\odot = 0.0211$, which is higher than the AS09 and much closer to the GS98 one.

---

\(^1\) We adopt a simple scaling of the initial $^7\text{Li}$ abundance with the metallicity because we are mainly interested in reproducing the lithium depletion pattern, i.e. $\epsilon_{\text{Li}} - T_{\text{eff}}$, which is independent of the initial $^7\text{Li}$ abundance.
Our models are computed adopting the AS05 mixture, for consistency with the extended pre-MS tracks and isochrones database already provided by our group\(^2\) (Tognelli et al. 2011), whereas for the conversion of [Fe/H] into \((Y, Z)\) we prefer to use \((Z/X)_0 = 0.0181\) from the more recent AS09 heavy elements distribution. The inconsistency that may arise is negligible. Indeed, we verified that the effect on pre-MS models of adopting the AS05 or AS09 distribution in the opacity, once \(Z\) and \(Y\) have been kept fixed, is much lower than the variation produced by a change of \((Y, Z)\) related to the error on \((Z/X)_0\) (see Tognelli et al. 2011, and the following discussion).

For the uncertainty on \((Z/X)_0\), the commonly suggested value is about \(\pm 15\%\) (see e.g., Bahcall et al. 2004; Bahcall & Serenelli 2005). However, to take the difference between recent \((Z/X)_0\) determinations into account, i.e. GS98, AS09, and CL10, a larger uncertainty of about \(\pm 25\%\) to \(\pm 50\%\) on \((Z/X)_0\) is required. Thus, we use a final uncertainty of \(\pm 25/\pm 15\%\) on \((Z/X)_0\).

Besides the uncertainties on \(Y_p\), \(\Delta Y/\Delta Z\), and \((Z/X)_0\), the initial \(Y\) and \(Z\) abundances are obviously also affected by the observational error on [Fe/H]. Generally the errors quoted in the literature vary from about \(\pm 0.01\), probably underestimated, to \(\pm 0.1\). Here we adopt as a conservative error \(\Delta [\text{Fe/H}] = \pm 0.05\).

By means of Eqs. (1) and (2), taking the quoted uncertainties into account, we obtain eight values of \((Y, Z)\) for each of the selected clusters, for which we compute pre-MS models. More precisely, the different \(Y\) and \(Z\) values are calculated by adopting, in turn, the minimum and the maximum values of one of the four parameters ([Fe/H], \(Y_p\), \(\Delta Y/\Delta Z\), and \((Z/X)_0\)), while the others are kept fixed to their central value. We computed two additional models with the maximum and minimum values of the estimated initial \(^7\)Li abundance, which, as already mentioned in Sect. 3, is set to \(e_{L_i} = 3.2 \pm 0.2\). Obviously a change in the initial chemical composition also affects the position of the star in the colour–magnitude diagram, hence the age and mixing length parameter determination. This effect has been taken into account (see Sect. 5.1).

Another source of uncertainty related to the stellar chemical composition that has to be considered is the assumed distribution of heavy elements, at fixed \(Z\), which strongly affects opacity values (Sestito et al. 2006). Since the opacity determines the temperature gradients and thus the extension of the convective envelope (in mass and temperature), a variation in this quantity, due to the uncertainty on the adopted mixture, modifies the lithium-burning rate and its resulting surface abundance.

Figure 1 shows the relative differences among the OPAL radiative opacity tables\(^3\) computed by adopting the GN93, GS98, AS05 (our reference model), and AS09 solar mixtures. To make the figure much clearer, we also show a box representing the region covered by the entire convective envelope for stellar models with masses in the range \(0.6–1.2\ M_\odot\) (thick-dashed box), for the same chemical composition of the opacity tables and adopting the mixing length value \(\alpha = 1.00\).

\(^2\) The database contains a very large grid of pre-MS models and isochrones between 1–100 Myr (for more details see, Tognelli et al. 2011). The corresponding database is available at: http://astro.df.unipi.it/stellar-models/

\(^3\) We use the OPAL opacity table released in 2005 for log \(T[K] > 4.5\), which are available at the url, http://opalopacity.llnl.gov/opal.html. For lower temperatures we use the Ferguson et al. (2005) radiative opacity, available at the url, http://webs.wichita.edu/physics/opacity/
4.3. Equation of state

Owing to the complexity of the evaluations of the various thermodynamical quantities, which are strictly correlated among each other, it is very difficult to assess a precise uncertainty on the EOS tables. An idea of how the current indetermination on the EOS propagates into stellar evolutionary predictions can be obtained by computing models with two different EOS tables that have been widely adopted, namely the OPAL EOS 2006 (our reference one) and PTEH (Pols et al. 1995). The comparison between the OPAL and the PTEH is useful to assess the effect of adopting a completely different treatment of the gas in stellar conditions, the two EOS being computed, respectively, in the formalism of the physical and chemical picture (see e.g., Trampedach et al. 2006).

4.4. $^7\text{Li}(\alpha, \alpha)\alpha$ cross section

Lithium destruction is obviously dependent on the $^7\text{Li}(\alpha,\alpha)\alpha$ cross section. However, the current uncertainty on the quoted reaction rate for bare nuclei is quite small (a few percent see e.g., Angulo et al. 1999; Lattuada et al. 2001), so that the effect on $^7\text{Li}$ abundance of such error is very small compared to the other error sources. We adopt the value of $\pm5\%$ as a conservative uncertainty on this quantity.

4.5. Total uncertainty on $^7\text{Li}$ surface abundance predictions

The partial uncertainty due to each parameter/physical input was obtained by the difference between the reference model, which is the one computed with the reference values of all the parameters, and the model computed by varying such parameter. This procedure was iterated for all the uncertainty sources discussed in the text. Then, the total error on surface lithium abundance predictions was computed by quadratically adding all the partial errors. We want to emphasize that the uncertainty analysis was performed for all the chemical compositions suitable for the selected clusters. Thus, for each cluster, error bars consistent with its chemical composition, mixing length parameter, and age were evaluated.

5. Surface lithium abundance: theory vs. observations

5.1. Young open clusters

The clusters age and the mixing length parameters for MS stars are determined by comparing the observed CMDs with the present theoretical isochrones. The age is largely affected by the lack of stars near the overall contraction region of such stars. The influence of the adopted EOS on the location in the HR diagram has already been discussed in several papers for both pre-MS evolution (see e.g., Mazzitelli 1989; D’Antona 1993; Tognelli et al. 2011) and low-mass MS stars (see e.g., Dorman et al. 1989; Neece 1984; Chabrier & Baraffe 1997; di Criscienzo et al. 2010). Here, we simply recall that the models are particularly affected by the EOS in all the phases where a thick convective envelope is present, i.e. the pre-MS or MS structures of low- and very low-mass stars. In these phases, when lithium burning is efficient, the resulting surface $^7\text{Li}$ abundance is quite sensitive to the adopted EOS, too, as shown in the bottom panel of Fig. 2. As noticed above, surface lithium abundance gets less affected by the EOS change as the mass increases, because of the progressively reduction of the burning efficiency.

Fig. 2. Comparison among the surface lithium abundance obtained with our reference set of tracks (solid line) and models with different assumptions on the adopted physical inputs, for $M = 0.6$, 0.8, 1.0, and 1.2 $M_\odot$ with $Z = 0.01291$, $Y = 0.274$, and $\alpha = 1$. Upper panel: effect of the change of the solar mixture (GN93, GS98, AS05, and AS09 ones) in the opacity tables. Bottom panel: effect of adopting the OPAL 2006 and PTEH EOS.
Table 1. Main properties adopted/derived for the five selected open clusters.

| Cluster | [Fe/H] | (Y, Z) | α_{MS} | Age (Myr) | Age (Myr) |
|---------|--------|--------|---------|-----------|-----------|
|         |        |        |         | (Λ_{0} = 0) | (Λ_{0} = 0.2) |
| Ic 2602 | +0.00$^a$ | (0.274, 0.0129) | 1.68 ± 0.1 | 40 ± 10 | 55 ± 10 |
| α Per   | −0.10$^b$ | (0.269, 0.0104) | 1.68 ± 0.1 | 60 ± 10 | 75 ± 10 |
| Blanco1 | +0.04$^c$ | (0.276, 0.0141) | 1.90$^{+0.5}_{-0.4}$ | 110 ± 30 | 130 ± 30 |
| Pleiades | +0.03$^d$ | (0.276, 0.0138) | 1.90$^{+0.5}_{-0.4}$ | 120 ± 20 | 130 ± 20 |
| NGC 2516 | −0.10$^e$ | (0.269, 0.0104) | 1.90 ± 0.1 | 130 ± 20 | 145 ± 20 |
|         | +0.07$^f$ | (0.278, 0.0150) | 1.90 ± 0.1 | 130 ± 20 | 145 ± 20 |

Notes. The columns list, respectively, the cluster’s name, [Fe/H], initial helium and metal abundance (Y, Z), the mixing length parameter calibrated on MS stars (α_{MS}), the best fit age without core overshooting, and the best fit age with a core overshooting parameter set to Λ_{0} = 0.2.

E. Tognelli et al.: $^7$Li surface abundance in pre-main sequence stars

Models computed with α_{PMS} = α_{MS} partially agree with data only in the case of α Per for M ≥ 0.7 M_⊙ and NGC 2516 if the low photometric [Fe/H] value is adopted (bottom left panel of Fig. 3). If the spectroscopic [Fe/H] value is used for NGC 2516, the predictions, as the other clusters, do not match the observations for M ≤ 1 M_⊙. However, we emphasize that, for these two clusters, models and data are compatible each other because of the large $^7$Li abundance scatter present among stars with similar T_{eff} (about 1 dex), combined with the large error bars on theoretical predictions.

Since in most of the cases the models with α_{PMS} = α_{MS} disagree with the data, and given the high sensitivity of $^7$Li surface abundance predictions to the convection efficiency, it is worth exploring the possibility that the mixing length parameter value varies from the pre-MS to the MS phases. Indeed, a possible dependence of α on the evolutionary phase (and/or gravity, T_{eff}-mass) is suggested from both observations and hydrodynamical simulations, as discussed in the introduction. Thus, we computed models with different values of α_{PMS}, namely, α_{PMS} = 1.0, 1.2, 1.4, 1.68, and 1.9, once α_{MS} and the ages have been fixed by the comparison in the CMD. Figure 3 shows the comparison between our “best fit” models and $^7$Li data for each cluster (dotted lines and filled red squares). The theoretical error bars computed for each cluster are also shown.

We emphasize that a satisfactory agreement with all the clusters in the sample (with the exception of the Pleiades) can be achieved by assuming the same pre-MS convection efficiency, namely α_{PMS} = 1.0. Such low-convection efficiency models are able to reproduce, within the error bars, the mean depletion profile even for low-mass stars, especially in the case of Ic 2602 and α Per.

As shown in Fig. 3, the poorest match between theory and data is achieved for the Pleiades. The hottest stars are nearly compatible within the error bars with the observations, which show a surface abundance about 0.2–0.3 dex lower than the predicted one. A possible way to improve the agreement with these stars is to adopt an initial lithium abundance of about ε_{Li} ≃ 3. However, this method does not improve the agreement with the low-mass stars, a problem still largely discussed in the literature (see e.g., King et al. 2000; Jefrides 2000; Umezu & Saio 2000; D’Antona & Montalbán 2003; Clarke et al. 2004; Xiong & Deng 2006; King et al. 2010, and references therein).

The results we obtain for young open clusters confirm the partial results of previous analysis, which have noticed that models with low-convection efficiency during pre-MS phase agree much better with lithium observation than those with solar or MS calibrated values (see e.g., Ventura et al. 1998; D’Antona & Montalbán 2003; Landin et al. 2006).
Fig. 3. Comparison between our model predictions and observational data (filled circles) for surface lithium abundance, for the selected sample of young open clusters, namely (from the top left panel), IC2602, α Per, Blanco 1, Pleiades, and NGC 2516. In each panel we show both the low-convection efficiency ($\alpha_{\text{PMS}} = 1.0$, red-filled squares and dotted line) and the high-convection efficiency models ($\alpha_{\text{MS}} = \alpha_{\text{MS}}$, dashed line and small black-filled squares). We also plotted the mass and the corresponding theoretical uncertainties on both the effective temperature and lithium abundance, for low- and high-convection efficiency models.

5.2. Binary stars

Binary systems and, in particular, the subclass of detached double-lined eclipsing binaries (EBs) are severe tests for stellar models. Indeed, for EBs independent measurements of mass, radius, and effective temperature are available (for a detailed review see e.g., Mathieu et al. 2007).

The validity of our theoretical models have already been tested against a large sample of pre-MS binaries (26 objects) by Gennaro et al. (2012), using the models of the Pisa pre-MS database against observations by means of a Bayesian method. The present pre-MS models differ from those available in the quoted database only in the minimum value of the mixing length parameter, i.e. $\alpha = 1.0$ instead of $\alpha = 1.2$. 
Table 2. Main parameters adopted for the selected set of EBs stars.

| System                     | Mass $[M_\odot]$ | log $L_{\text{eff}}$ [K] | log $L/L_\odot$ | $\epsilon_{\text{Li}}$ | [Fe/H] |

Notes. For ASAS J052821+0338.5 (a) and (b) components we used the averaged value of [Fe/H] = -0.15 when computing the models.

References. (a) Stempels et al. (2008); (b) Martin & Rebolo (1993); (c) Covino et al. (2000); (d) Stassun et al. (2004); (e) Stempels et al. (2008); (f) Martin & Rebolo (1993); (g) D’Orazi et al. (2009).

From the sample of EBs presented in Gennaro et al. (2012), we selected a subsample of binary systems for which surface lithium abundances are available, namely ASAS J052821+0338.5 (Stempels et al. 2008), EK Cep (Popper 1987), RXJ 0529.4+0041 A (Covino et al. 2004), and V1174 Ori (Stassun et al. 2004). Table 2 summarizes the main parameters of each system: mass, effective temperature, luminosity, lithium abundance, and [Fe/H]. The corresponding models are computed for $\alpha_{\text{PMS}} = 1.0, 1.2,$ and 1.68.

Figure 4 shows the HR diagram of the four selected systems compared with our evolutionary tracks. Gennaro et al. (2012) have already shown that theoretical models with low initial
helium abundance and mixing length parameter agree better with the data of pre-MS binary systems, in particular for those ones with at least one component near the Hayashi track. In our sample only EK Cep does not have stars near the Hayashi track.

For ASAS J052821+0338.5 (Fig. 4), both the lowest and the highest \( \alpha_{\text{PMS}} \) values are compatible with the primary star, whereas \( \alpha_{\text{PMS}} \approx 1.0-1.2 \) is required to match the secondary. For EK Cep we cannot constrain the mixing length value during the pre-MS since both stars are approaching the ZAMS, and consequently their position in the HR diagram is not sensitive to the choice of \( \alpha_{\text{PMS}} \). Moreover, we can not achieve a satisfactory agreement between our model and the primary star, as already pointed out by Gennaro et al. (2012). Similarly to ASAS J052821+0338.5, RXJ 0529.4+0041 A has two stars near the "heel". As shown in Fig. 4, the three different \( \alpha_{\text{PMS}} \) are all compatible with both stellar components within the observational uncertainties, which are quite large.

V1174 Ori is much more problematic. As discussed in Gennaro et al. (2012), the two stars show a peculiar position in the HR diagram. None of the present models (or other models widely adopted in the literature) can reproduce the correct position of the secondary by adopting the measured mass and chemical composition. A possible explanation of such a peculiar position in the HR diagram can be the presence of a large systematic uncertainty introduced by the adopted spectral type-effective temperature scale (see e.g., Luhman et al. 1997; Stassun et al. 2004; Hillenbrand & White 2004; Gennaro et al. 2012). To be close to our coolest model (\( \alpha_{\text{PMS}} = 1.0 \)), an increase of about 300 K in the secondary effective temperature would be required, which would correspond to a primary effective temperature increment of about 400 K. However, it seems unlikely that such a large shift could be caused uniquely by the adoption of a inadequate spectral type-effective temperature scale.

Figure 5 shows the comparisons between theoretical and observed lithium surface abundances. The evolutionary track of surface lithium abundance is shown. In the case of EK Cep we do not show the primary because the lithium abundance is not currently available. The figure shows the tracks computed with \( \alpha_{\text{PMS}} = \alpha_{\text{MS}} = 1.0 \) are in good agreement with data for the primary components (1.0 \( \neq M \neq 1.4 \)) within the uncertainties, since lithium depletion is almost negligible for such masses. Therefore, the primary components belonging to our sample do not allow further constraints on the \( \alpha_{\text{PMS}} \) value. In contrast, the impact of \( \alpha_{\text{PMS}} \) gets stronger and stronger as the mass decreases below about 1 \( \neq M \). The secondary of EK Cep and RXJ 0529.4+0041 A might thus give useful
5 The case of V1174 Ori is peculiar, and if the problem resides in the effective temperature determinations, then lithium abundances could also be affected by uncertainties greater than the quoted ones.

Acknowledgements. It is a great pleasure to thank Matteo Dell’Omodarme for his invaluable help in computer programming and Paola Sestito for useful and pleasant discussions. This work was made use of the WEBDA database, operated at the Institute for Astronomy of the University of Vienna. This research has been partially supported by the PRIN-INAF 2011 (Tracing the formation and evolution of the galactic halo with VST, P.I. Marcella Marconi).
