Abstract

We have searched for third generation leptoquarks ($LQ_3$) using 1.05 fb$^{-1}$ of data collected with the D0 detector at the Fermilab Tevatron Collider operating at $\sqrt{s} = 1.96$ TeV. We set a 95% C.L. lower limit of 210 GeV on the mass of a scalar $LQ_3$ state decaying solely to a $b$ quark and a $\tau$ lepton.

PACS numbers: 13.85.Rm, 14.80.–j
The standard model (SM) provides a good description of experimental data to date, but fails to address the disparity between the electroweak scale and the much higher grand unification or Planck scale. Models invoking new strong coupling sectors [1], grand unification [2], superstrings [3], or quark-lepton compositeness [4] may alleviate this problem. In these models, new leptoquark particles ($LQ$) carrying both lepton number and color charge quantum numbers may arise. The observed suppression of flavor changing neutral currents implies that a particular $LQ$ state should couple only to quarks and leptons of the same fermion generation. Thus the third generation $LQ$ ($LQ_3$) will decay only into a $b$ or $t$ quark and a $\tau$ or $\nu_\tau$, depending on the $LQ_3$ electric charge. At the Fermilab Tevatron $p\bar{p}$ Collider, leptoquarks can be pair-produced through gluon-gluon fusion and $q\bar{q}$ annihilation with standard QCD color interactions. The charge $4/3$ $LQ_3$ decays to $\tau^+\bar{b}$ with a branching ratio (BR) of 1, whereas the charge $2/3$ $LQ_3$ decays to $\tau^+b$ with coupling constant $\beta$ and to $\tau_\tau t$ with coupling $(1-\beta)$ (and charge conjugates for $LQ_3$ decays). For the $\tau_\tau t$ decay, the BR $= (1-\beta) \times f_{PS}$ is further suppressed by the phase space factor $f_{PS}$ due to the large top quark mass.

In Run II, the D0 collaboration set a lower mass limit of 229 GeV [5] for the charge $1/3$ $LQ_3 \to \nu_\tau \bar{b}$. Here we present new limits on the mass of leptoquarks with charge $4/3$ with decays $LQ_3 \to \tau \bar{b}$ and charge $2/3$ with decays $LQ_3 \to \tau \bar{b}$. The best previous limit for this channel is 99 GeV [6, 7]. For pair production, both $LQ_3$ charge states lead to the final state $\tau^+\tau^-b\bar{b}$. We identify one of the $\tau$ leptons through its decay $\tau \to \mu \nu_\mu \nu_\tau$ and the other through its hadronic decays. The presence of jets from $b$ quarks is signalled by tracks displaced from the primary vertex. The final state sought is thus two $b$ jets, $\mu$, $\tau$, and missing transverse energy ($E_T$).

The D0 detector [8, 9] has a central tracking volume with a silicon microstrip vertex detector (pseudorapidity coverage $|\eta| < 3$) and a scintillating fiber tracker ($|\eta| < 2.5$) within a 2 T solenoidal magnet; a uranium/liquid-argon calorimeter ($|\eta| < 4.2$); and a surrounding muon identification system ($|\eta| < 2$), with tracking chambers and scintillators before and after solid iron toroid magnets. Events are selected using a suite of triggers requiring either a single muon or a muon in association with jets. This analysis is performed using 1.05 fb$^{-1}$ of data collected in Run II.

Muon candidates are required to have hits in the muon system matched to a track candidate with $p_T > 15$ GeV and $|\eta| < 2$, and are required to extrapolate to within 1.5 cm of the
reconstructed primary vertex along the beam axis. Cosmic ray muons are removed using the muon scintillation counter timing. Muon candidates are required to be isolated from nearby particles by requiring a calorimeter energy deposit of less than 2.5 GeV within a hollow cone of $0.1 < R < 0.4$ centered on the muon direction, and less than 2.5 GeV associated with tracks (excepting the muon track) within $R < 0.5$. Here, $R = \sqrt{(\Delta \phi)^2 + (\Delta \eta)^2}$ is the distance in $\eta$-$\phi$ space between objects.

We identify three types of tau candidate motivated by the decays: (1) $\tau^\pm \to \pi^\pm \nu$, (2) $\tau^\pm \to \pi^\pm \pi^0's \nu$, and (3) $\tau^\pm \to \pi^\pm \pi^\mp (\pi^0's) \nu$. The corresponding selections for the three types are based on tracks with transverse momenta $p_{Ttrk} > 1.5$ GeV and energy clusters in the electromagnetic (EM) calorimeter, both within a cone of $R < 0.5$. The visible transverse momentum of a tau candidate, $p_T$, is constructed from the calorimeter transverse energy ($E_T^\tau$), corrected by track information where warranted. The tau selections are (1) a single isolated track with transverse momentum $p_{Ttrk} > 15$ GeV and no nearby electromagnetic energy cluster; (2) a single isolated track with $p_{Ttrk} > 7$ GeV with an associated EM cluster; and (3) two or more tracks, with at least one having $p_{Ttrk} > 7$ GeV, with or without associated EM clusters. Tau candidates must have $p_T$ above 15 GeV for types 1 and 2, and above 20 GeV for type 3. For type 1 candidates, we require $p_{Ttrk}/E_T^\tau \geq 0.7$ to reduce contributions from $\tau^\pm \to \pi^\pm \pi^0's$ in calorimeter regions with poor EM particle identification and $p_{Ttrk}/E_T^\tau \leq 2.0$ to reduce backgrounds from muons. A neural network is formed for each $\tau$ type using input variables such as isolation and the transverse and longitudinal shower profiles of the calorimeter energy depositions associated with the tau candidate. The networks give an output variable $N_i$ for $\tau$-type $i$. We require $N_1, N_2$ and $N_3$ to exceed 0.9, 0.9 and 0.95, corresponding to about 70% efficiency with $\geq 90\%$ rejection of fake jets.

We reconstruct jets using calorimeter energy deposits within a cone radius of 0.5 and correct to the particle level using a jet energy scale correction (JES). Jets containing a muon are further corrected for the muon and average neutrino energies. Jets are required to have $p_T > 20$ GeV ($> 25$ GeV for the highest $p_T$ jet) and $|\eta| < 2.5$ relative to the center of the detector. We calculate $E_T$ from the transverse plane vector sum of calorimeter energy deposits, corrected for observed muons and for the jet and $\tau$ energy scale corrections.

We tag jets as $b$-jet candidates using a neural network algorithm employing track impact parameters, significance of track displacement from the primary vertex, vertex mass, and number of tracks associated with a secondary vertex. The selection on the neural
FIG. 1: Comparisons of data and the sum of backgrounds for (a) \(p_T\) of the highest \(p_T\) jet after preselection, (b) \(m^*\) after preselection, and (c) \(S_T\) for the 1 and \(\geq 2\) \(b\) tagged samples combined. We denote the diboson contribution as “db”, heavy quarks \((b, c)\) as “hf” and light partons \((u, d, s\) and gluons) as “lp”. The \(LQ_3\) signal is shown for \(m_{LQ_3} = 200\) GeV, multiplied by 10 in (a) and (b) and without scaling in (c). (color online)

network output is optimized for the best \(LQ_3\) sensitivity and has 72% efficiency for \(b\) jets, with a misidentification probability for light quark jets of 6%.

Events are preselected with the requirements that there is only one isolated muon, and at least two jets with \(R > 0.5\) relative to the \(\mu\) or \(\tau\) candidates. If more than one \(\tau\) candidate is found, the one with the largest \(p_T\) is chosen. We require no electrons with \(p_T > 12\) GeV.

The \(LQ_3\) signal is simulated for \(m_{LQ_3} = 120\) to \(220\) GeV in \(20\) GeV steps, using the \textsc{pythia} \[13\] Monte Carlo (MC) generator and CTEQ6L1 \[14\] parton distribution functions (PDF). The normalization at next-to-leading order (NLO) is taken from \[15\]. The \(\bar{t}t\) and \(W/Z\) boson+jets backgrounds are simulated with the \textsc{alpgen} MC generator \[16\], with \textsc{pythia} used for parton showering and fragmentation. The \(\bar{t}t\) cross section is normalized to the NNLO cross section \[17\] with top quark mass \(m_t = 175\) GeV and the \(W/Z\) +jets cross sections are normalized to the \(W/Z\) inclusive NLO cross section \[18\]. The \(WW\), \(WZ\), and \(ZZ\) diboson backgrounds are generated using \textsc{pythia} and normalized to the NLO cross sections \[18\]. The \(\tau\) polarization and decays for all processes are simulated with \textsc{tauola} \[19\]. The simulated events are processed through a \textsc{geant} \[20\] detector simulation and the standard D0 event reconstruction. They are further corrected for differences between data and MC simulation in the identification efficiencies for muons, electrons and jets, \(Z\) boson \(p_T\), the distribution of primary vertices along the beam axis, jet energy scale and resolution, \(b\)-jet tagging, and the effect of additional minimum bias interactions. The trigger efficiency applied to the simulated events is measured as a function of muon and jet azimuthal
angle $\phi$ and $\eta$, and is appropriately averaged using the instantaneous luminosity in each data collection epoch.

We determine the multijet (MJ) background from two data samples, after subtracting the simulated SM backgrounds for both. The signal (SG) sample is that obtained from the preselected data discussed above. The enhanced background (BG) sample uses the preselection cuts, except that the muon track and calorimeter isolation requirements are reversed, and the $\tau$ identification requires $N_i < 0.8$. The shapes of the BG kinematic distributions agree well with those for the SG sample and provide the shape of the MJ background. We subdivide both SG and BG samples into opposite sign (OS) and same sign (SS) subsets according to whether the observed $\mu$ and $\tau$ charges are opposite or the same, with numbers of events, $N_Q^C$ ($C=$SG,BG) ($Q=$OS,SS). The MJ background is computed as $N_{\text{SG}}^{\text{OS}} = f \times N_{\text{SS}}^{\text{SG}}$, where the MJ normalization factor is $f = N_{\text{OS}}^{\text{BG}}/N_{\text{BG}}^{\text{SS}}$. The factor $f$ is observed to be close to 1 and independent of $p^\mu_T$ and $p^\tau_T$. There is negligible $LQ_3$ signal in the SS BG subsample.

Further analysis uses the OS preselected events. Figure 1(a) shows the $p_T$ distributions of the data and the sum of all backgrounds for the highest $p_T$ jet. The agreement for this and other kinematic distributions is good. Figure 1(b) shows the data and background distributions for a variable related to the $W$ boson mass, defined as $m^* = \sqrt{2E\mu E\nu(1 - \cos \Delta\phi)}$ where the estimated neutrino energy is $E\nu = E_T(E\mu/p^\mu_T)$, and $\Delta\phi$ is the azimuthal angle between the muon and $E_T$ directions. The $t\bar{t}$ and $W +$ jets backgrounds contain a real $W$ boson and have a high value of $m^*$, whereas the $LQ_3$ signal tends to have small $m^*$. Based on the expected $LQ_3$ mass limit from MC studies, we require $m^* < 60$ GeV.

The jets in the event sample after the $m^*$ cut are subjected to the $b$-tagging algorithm and subsets are formed with exactly one tagged $b$ jet and with $\geq 2$ $b$ jet tags. The numbers of events in the OS preselection sample, after the $m^*$ requirement, and the 1 and $\geq 2$ $b$-tagged jet subsamples, are shown in Table [I].

We define the variable $S_T$ as the scalar sum of the transverse momenta of $\mu$, $\tau$, the two highest $p_T$ jets, and $E_T$. The $LQ_3$ signal is expected to have higher values of $S_T$ than the background processes. Figure 1(c) shows the distributions of $S_T$ for data and expected background, for the 1 $b$-tagged jet and $\geq 2$ $b$-tagged jet samples combined. We observe no excess above the expected backgrounds.

The systematic uncertainty for the luminosity determination (6.1%) is taken from [21].
TABLE I: Number of events for data and estimated backgrounds at the preselection level, after the \( m^* \) cut (before \( b \)-jet tagging), and for the 1 \( b \)-tag and \( \geq 2 \) \( b \)-tag subsets. Light partons \((u,d,s,g)\) are denoted as “lp”. Also shown is the expected number of signal events for \( m_{LQ_3} = 200 \) GeV.

Calibration data sets are used to determine the uncertainties on the trigger efficiency (3%) and on the reconstruction, identification and isolation efficiencies for the \( \mu \), \( \tau \), and jets (7%). The MC acceptance uncertainties due to the jet energy uncertainty are found to be 6 – 9% by varying the JES by \( \pm \) one standard deviation [22]. The uncertainties on the tagging rates for heavy flavor and light parton jets result in systematic uncertainties on the signal acceptance (7.5%), and on the \( W/Z + \) heavy flavor jets background (7.5%) and \( W/Z + \) light parton jets background (15%) [12]. The MJ background uncertainty (15%) is determined by using independent MJ data samples in which either the \( \mu \) isolation cuts or the \( \tau \) neural network cuts (but not both) are reversed. The \( t\bar{t} \) cross section uncertainty (18%) incorporates the estimated theoretical dependence on the renormalization and factorization scales [17], the uncertainty on \( m_t \) and the uncertainty due to the PDF choice. The diboson production cross section uncertainty (6%) and the \( W/Z + \) jets cross section uncertainties (22%) are estimated using MCFM [18].
We compute the 95% C.L. upper limits on the signal cross section as a function of $m_{LQ_3}$ using the modified frequentist method \cite{23} as implemented in \cite{24}. Negative log-likelihood ratio (LLR) test statistics are formed and combined from the $S_T$ distributions for 1 and $\geq 2$ $b$-tagged samples in simulated pseudo-experiments, under the background only (LLR$_b$) and signal plus background (LLR$_{s+b}$) hypotheses. We integrate LLR$_b$ (LLR$_{s+b}$) above the LLR value observed in data to obtain confidence levels CL$_b$ (CL$_{s+b}$). The $LQ_3$ cross section is varied until the ratio CL$_s = CL_{s+b}/CL_b$ equals 0.05. The resulting expected and observed limits are shown in Fig. 2, together with the theoretical cross section ($\sigma_{th}$) assuming BR = 1. The observed cross section limit is within one standard deviation of the expected limit for $m_{LQ_3} \approx 200$ GeV, and within two standard deviations for all masses. The uncertainty on $\sigma_{th}$ is obtained by varying renormalization and factorization scales by a factor of two above and below the central value of $m_{LQ_3}$ and by taking into account the uncertainties in the PDFs \cite{14,25}. The intersection of the observed cross section limit and the central $\sigma_{th}$ as a function of $m_{LQ_3}$ yields the exclusion of $m_{LQ_3} > 210$ GeV (for $\beta = 1$), and at the one standard deviation lower value of $\sigma_{th}$ we find $m_{LQ_3} > 201$ GeV, both at the 95% C.L.

The dashed line in Fig. 2 indicates the decrease in the cross section $\times$ BR$^2$ for the charge $2/3$ $LQ_3 \to \tau b$ when the decay $LQ_3 \to \nu t$ becomes kinematically possible, after including $f_{PS}$ (for $\beta = 0.5$ and $m_t = 175$ GeV). In this case, we obtain $m_{LQ_3} > 207$ GeV for the central $\sigma_{th}$ and $m_{LQ_3} > 201$ GeV for the one standard deviation lower limit of $\sigma_{th}$, at 95% C.L.

In summary, we have searched for third generation leptoquark pair production with decays $LQ_3 \to \tau b$, and exclude $m_{LQ_3} < 210$ GeV at the 95% C.L., assuming the branching fraction for this mode to be one. This is the most stringent limit on third generation leptoquarks in this decay channel to date.

We thank the staffs at Fermilab and collaborating institutions, and acknowledge support from the DOE and NSF (USA); CEA and CNRS/IN2P3 (France); FASI, Rosatom and RFBR (Russia); CNPq, FAPERJ, FAPESP and FUNDUNESP (Brazil); DAE and DST (India); Colciencias (Colombia); CONACyT (Mexico); KRF and KOSEF (Korea); CONICET and UBACyT (Argentina); FOM (The Netherlands); STFC (United Kingdom); MSMT and GACR (Czech Republic); CRC Program, CFI, NSERC and WestGrid Project (Canada); BMBF and DFG (Germany); SFI (Ireland); The Swedish Research Council (Sweden); CAS and CNSF (China); and the Alexander von Humboldt Foundation (Germany).
FIG. 2: Observed and expected cross section limits at the 95\% C.L. of the pair production of third generation leptoquarks as a function of $m_{LQ_3}$. The uncertainty on the theoretical prediction is shown with shaded error bands. The theoretical cross section times branching ratio when $\beta = 1/2$ is shown as the dashed line. (color online)
