FIG. 1: Shape of the nullclines computed numerically from Eqs. (4) (green line) and (5) (orange line) at increasing $\varepsilon$ and $\alpha$ values. The directions of the flows are indicated with small arrows. Here the intersections of the nullclines are fixed points (black: stable, white: unstable). Depending on parameter values different equilibria are found: $P^*_1$ at the origin; $P^*_2$ at the vertical axis of the phase space and both $P^*_3$ (interior saddle point) and $P^*_4$ (interior stable node). The dynamics and basins of attraction can be seen in figure S???. The other parameters are fixed at: $r = 0$, $f = 0.9$, $\delta = 0.1$, $b = 0.6$, $c = 0.3$, $m = 0.15$, and $\beta = 0$. 

Synthetic soil crusts against green-desert transitions: a spatial model

FIG. 2: Dynamics within the phase space $(V, S)$ shown in Fig. S1 displaying the nullclines. The directions of the flows are indicated with small arrows, and some orbits are displayed. Here the basins of attraction of each fixed point are displayed with different colours: coexistence of vegetation with fertile soil (green); full desert state (red); coexistence between fertile and desert soil without vegetation (blue). Note the orbits are also shown with the colours of the basins they move in. The parameters are the same as in Fig. S1.
FIG. 3: Same as in Fig. S1 now increasing $\varepsilon$ and $\beta$, with $\alpha = 0$ and keeping all other parameters as in Fig. S1.
FIG. 4: Same as in Fig. S2 for the cases shown in Fig. S3, now increasing $\varepsilon$ and $\beta$, with $\alpha = 0$ and keeping all parameters as in Fig. S1.
FIG. 5: Stability of the fixed point $P^*_2$, with eigenvalues $\lambda_1 = d - \beta$ and $\lambda_2 = b(1 - d/\beta) - m$. This equilibrium is stable if $\lambda_1 < 0$ and $\lambda_2 < 0$ (green region). The grey region indicates the saddle behaviour, being stable in the $S$-axis and unstable in the $V$-axis. Finally, the white region displays the parameter values in which this equilibrium is a repeller.
FIG. 6: (a-d) Bifurcation diagrams obtained numerically from Eqs. (4-5) using $\varepsilon$ as bifurcation parameter and $(V(0) = 1, S(0) = 0)$ as initial conditions. At the right column we display time series for the fraction of vegetated area. Each diagram is built for different cases of the terraformation strategies by using different $\alpha$ and $\beta$ values, except for (a) that has not been terraformed. The displacement of the critical value of $\varepsilon$ due to terraformation is indicated with a light-violet area in the bifurcation diagrams. Note that the in all panels the vegetation becomes extinct due to a catastrophic transition at increasing $\varepsilon$. This transition is given by a saddle-node bifurcation between the interior equilibria $P_2^*$ and $P_3^*$. After the transition two possible states can be achieved: desert dominance ((a) and (b) with $\alpha = 1$ and $\beta = 1$) or coexistence between fertile soil and desert without vegetation ((c) and (d), with $\beta = 1$). All the time series show the evolution of the vegetated area: just after the bifurcation they experience a very long transient before extinction: a dynamical ghost or delayed transition. The dashed dark green line represents the stable vegetation area ($V^*$) before the transition. The parameters are the same as in Fig. S1.
FIG. 7: Equilibria of vegetation (a) and fertile soil (b) displayed in the parameter space $(\alpha, \varepsilon)$ keeping $\beta = 0$. We also display the change in the equilibrium states for the cuts shown on the surface (indicated with different colours fixing the value of $\alpha$ and $\varepsilon$). The bifurcation diagrams on the right display the equilibria at increasing for different values of $\alpha$ (using the same colour patterning than the 3D plots). We have labeled the different bifurcations that the system can experience for 3 values of $\varepsilon$ as examples (saddle-node (s-n) and transcritical bifurcations). The transparent blue area shows the values for which vegetation coexists with the fertile soil. The transparent green area means no vegetation and both fertile and desert soil. The transparent orange area corresponds to the full desert equilibrium. The other parameters are fixed as in Fig. S1.
FIG. 8: Same as in Fig. S7 now shown in the parameter space \((\beta, \varepsilon)\) with \(\alpha = 0\). The other parameters are fixed as in Fig. S1.
FIG. 9: Dynamical properties near the transition found in the spatial system using a lattice size of $50 \times 50$ sites. (a) Fraction of vegetated area ($V$) and of fertile soil ($S$) at increasing $\varepsilon$ for the non-terraformed system (the critical value is $\varepsilon_c \approx 0.26$) computed following the same procedure than in Fig. S9. Here fluctuations are larger due to the smaller lattice size. After the extinction, the vegetation suffers an extremely long delay due to a ghost (see the time series from the mean field model in Fig. 6). In (a.1) 5 realisations with extinction of vegetation are displayed close to the transition. Note the bottleneck is here also clearly visible. Panel (a.2) displays the region in the phase space ($V, S$) where the system spends more time to achieve the full desert state, indicating where the ghost is found. Panels (a.3) and (a.4) display the fraction of iterates accumulated at a given density. Here the peak of the distribution corresponds to the value of the variables found at the bottleneck regions of the ghost. In all panels in (b) we display the same analyses than in panels (a) for the terraformed system ($\alpha = \beta = 1$, here with $\varepsilon_c \approx 0.86$).
