Smoking in pregnancy: a cross-sectional study in China

Xianglong Xu 1,2,3, Yunshuang Rao 4, Lianlian Wang 5,6,7, Sheng Liu 1,2,3, Jeff J. Guo 8, Manoj Sharma 9 and Yong Zhao 1,2,3*

Abstract

Background: Findings on smoking among pregnant women were mostly from high income countries and were rarely from China. This study aimed to estimate the prevalence of smoking and its influencing factors among pregnant women living in China.

Methods: A cross-sectional analysis was conducted in this study. Data from pregnant women were collected in this study from June to August 2015 from 5 provinces of mainland China. A total of 2345 pregnant women were included in this study, the mean age of the participants was 28.12 years (SD 4.13).

Results: About 82.9% of smoking women quit smoking after they were pregnant. The prevalence of smoking among pregnant women was 3.8%. Among the participants, 40.0, 30.7, 1.8, 29.9, 0.8, 31.4, 31.2, and 26.7% had husbands, fathers-in-law, mothers-in-law, fathers, mothers, colleagues, friends, and relatives, respectively, who were smokers. Compared with pregnant women of basic education level (junior middle school or below), those of the higher education level (undergraduate or above) were at higher risk of smoking (OR, 5.17; 95% CI, 2.00–13.39). Compared with pregnant women from rural areas, urban pregnant women were less likely to be current smokers (OR, 0.55; 95% CI, 0.32–0.94). Compared with pregnant women whose mothers-in-law did not smoke, those whose mothers-in-law smoked were at higher risk of smoking (OR, 4.67; 95% CI, 1.87–11.70). However, compared with pregnant women whose husband did not smoke, those whose husband smoked were not significantly at higher risk of smoking (OR, 1.12; 95% CI, 0.73–1.73).

Conclusions: Most of smoking women quit smoking after they became pregnant. Tailored intervention programs to reduce smoking in pregnant women should focus on those with higher education level, from rural areas, and pregnant women whose mothers-in-law smoke.

Keywords: Smoking, Pregnancy, China

Background

Tobacco use and smoke exposure are critical health issues for pregnant women and their unborn babies [1]. Smoking during pregnancy is significantly associated with increased risks of intrauterine growth retardation [2], low birth weight [3], miscarriage [4], stillbirth [5], congenital malformation [5], early weaning [6], sudden infant death syndrome [7], genetic-related hereditary diseases [8], and childhood overweight [9]. In 2014, 52.9% of men in China were reported to be tobacco smokers, and only 2.4% of the women smoked [10].

Studies in many countries have reported that various factors associated with smoking during pregnancy. These factors include women of relatively young age, of less schooling, who are multiparous, who are exposed to passive smoking (from spouses and friends or colleagues), who have short sleep duration, and who drink [11], mothers born overseas, of higher socio-economic status, pregnant for the first time, and who attended early antenatal care [12]. Further pregnant women who live alone, have low education level (high school or less), have low health literacy, are housewives, have children, have partners who smoke, have unplanned pregnancy,
was categorized as non-manual (individual business/civil servants/senior manager and middle-level manager in large and medium enterprise/private entrepreneur/professionals/clerk/students), manual (rural migrant workers/industrial workers of non-agricultural registered permanent residence/business services staff), unemployed, and others [20].

Smoking status
Husband, father-in-law, mother-in-law, father, mother, colleague, friend, relative were divided into smokers and non-smokers. Colleague (at least one person defined as a smoker); Friend (at least one person defined as a smoker); Relative (at least one person defined as a smoker); currently smoking (defined as those who smoke during pregnancy).

Statistical analyses
The characteristics of the participants were summarized using frequencies and percentages and presented using descriptive analysis. Univariate logistic regression analysis and multivariable logistic regression analysis was utilized to probe factors affecting smoking among pregnant women. Factors were considered in the multivariate logistic regression modeling of factors that affect smoking among pregnant women: parity, education level, residence, career, trimester of pregnancy, smoking status of husband, smoking status of father-in-law, and smoking status of mother-in-law. Multivariate model was statistically significant in the model coefficient test ($p < 0.05$), and reached a good fit in Hosmer and Lemeshow test ($p = 0.9688$). All statistics were performed using a two-sided test, and statistical significance was considered at $p < 0.05$. Data analyses were performed using statistical software (SAS version 9.1.3; SAS Institute, Cary, NC, USA).

Results
Characteristics of participants
A total of 2345 pregnant women were included in this study, including 1755 [74.84%] pregnant women of first pregnancy. The mean age of the participants was 28.12 years (SD 4.13). 164 (6.99%) women smoked prior to pregnancy among those smokers, 136(82.9%) quitted smoking after they were pregnant. Overall, the prevalence of smoking was 90 [3.8%] (74.4 and 25.6% women of first and second pregnancies, respectively). (Please see Table 1).

Univariate logistic regression model for identifying factors that affect smoking in pregnancy
Univariate logistic regression model for identifying factors affect smoking among pregnant women (Please see Table 2). Compared with pregnant women of basic education level (junior middle school or below), those of higher education level (senior college and university or above) were at higher risk of smoking (OR, 3.88; 95% CI,
### Table 1 Characteristics of pregnant women, China, 2015 (n, %)

| Variable                                      | All participants | Smoker | Non-smoker |
|-----------------------------------------------|------------------|--------|------------|

smoking among pregnant women than those in their first pregnancy (OR = 1.19, 95% CI = 0.73, 1.96).

Discussion
The family planning policy of China was introduced in 1979 to slow the population growth rate of the nation. At the end of 2013, “Selective Two-Child Policy” was introduced China’s amendment to its 1978 single-child family policy, and it allowed couples nationwide to have a second child if either parent is an only child. Then, on 29 October 2015, the Chinese government announced the “2nd-child policy”, fully enabling couples to have two children. This means that more pregnant women and pregnant women in their second pregnancy in the future. Health behavior and health during pregnancy are worthy of attention. Smoking behavior is a critical health issue for pregnant women. This study found that the prevalence of smoking was 3.8%, which was higher than the smoking rate of women in general (2.4%) [21]. Possible reason is that pregnant women in this study of higher education level are more likely to smoke, and 67.8% of participants in this study were in higher education level. Although a study found that first time mothers showed an increased likelihood of smoking cessation during pregnancy [12], this study found second time mothers were not significantly correlated with low smoking during pregnancy in this study.

This study found that pregnant women of the higher education level (senior college and university or above) were at higher risk of smoking than those of the basic education level. This study is different from the study in Japan, in which the prevalence of smoking was significantly higher among pregnant women with less schooling [11]. Education was different because of the different social systems and cultures. We hypothesize the possible reason to be that persons with high education level do not necessarily have high health literacy and health knowledge levels. Most Chinese with higher education level focus on their own professional learning, and they may acquire little health literacy and health knowledge. A previous study showed that no statistically significant correlations existed between smoking cognition and behavior among young male smokers in a sample with higher education in China [22]. People with high levels of health literacy are more likely to engage in health-promoting behaviors and therefore have better health [23]. Another possible reason is that most women with higher education level have jobs, and they may be affected by the environment, for example, the male colleague smokers. The reason behind that the high proportion of smoking rate among pregnant women of higher education level remains undetermined, and further research will be needed to probe the reasons.

This study found that compared with rural pregnant women, urban pregnant women were less likely to be current smokers. We hypothesize the possible reason to be that rural pregnant women are more likely to be lack of antenatal care than urban pregnant women. A previous study found that lack of antenatal care in the first trimester was strongly associated with increased risk of smoking during pregnancy [12]. Secondly, smoking culture is widely popular in rural areas, more than half of them live in rural areas in China [24], and smoking prevalence in rural areas was higher than in urban areas [25]. Among current and former smokers, sharing cigarettes in China was a major impediment to smoking cessation [26]. In addition, this may be related to the

| Parameter | OR (95% CI) | p-value |
|-----------|------------|---------|
| Parity | | |

difference between rural and urban settings on the maternity care during pregnancy in China, such as maternity care institutions, the quality of hospital, health-rated information and health education. Persons in rural areas have limited access to health education information. Consequently, rural residents have low level of health literacy. A previous survey showed that the scientific literacy level of urban residents in 2015 was 9.72%, which was higher than that of rural residents (2.43%) [27]. Compared with health education activities in urban areas, rural areas have limited health education activities. Thus, pregnant women in rural areas may be unaware of the harm of smoking during pregnancy. Consequently, the active promotion of antismoking education in rural, poverty-stricken, and less developed areas is important. This study may indicate that strengthening the constructions of rural popular science of public service and scientific information is necessary.

This study found that pregnant women whose mothers-in-law smoked were at higher risk of smoking than those whose mothers-in-law did not smoke. However, this study also found that smoking status of husband and smoking status of father-in-law did not significantly with the risk of smoking among pregnant women. Smoking behavior by social network members increases the likelihood of smoking, and this effect appears to generalize to pregnant women in China. We hypothesize the possible reason to be that most women in China live with their husband’s family and not with their parents after marriage. Married women may have more contact with their husband’s parents. Thus, some behavior or habits of pregnant women are more susceptible to the influence of mothers-in-law. The positions of mothers-in-law in their home are higher in the eyes of pregnant women, thus the impact on pregnant women in terms of smoking. Although the rates of smoking among husbands are high, the influence of peers and husband is small and not statistically significant in China, which is different from that in Western population. Studies found that peer influence (husband, colleagues, and relatives) has a role in the smoking of pregnant woman [2, 28]. Our study found that pregnant women smokers received more pressure from mothers-in-law than from husbands, fathers-in-law, fathers, mothers, colleagues, friends, and relatives. Proximal factors include peer influence, which is often expressed as peer pressure [29]. The proximal and distal psychological risk factors of smoking behavior and intervention vary based on the cultural context [28]. This study provides some directions and insights for future health education on tobacco control among pregnant women. Health educators not only need to focus on pregnant women but also on mothers-in-law of pregnant women in future health education on smoking, especially for pregnant women.

This study has certain limitations. First, cross-sectional survey data reduced the ability to make direct causal inferences, explore whether unmeasured factors may better explain the observed relationships we observed, and determine the direction of causality. Second, the face-to-face interview survey may have resulted in information bias. Some smoking respondents may not have answered the questions truthfully. Some smokers may report that they were non-smokers, and this could underestimate the prevalence of smoking among pregnant women. However, all questions in the survey were reviewed by a research panel and the participants in the pilot study. Thus, the questionnaire was less likely to have included items that could be perceived as sensitive by the study participants. Third, our study was not exactly nationally representative. The sample consisted of pregnant women in five regions of China, namely, Chongqing, Chengdu, Zunyi, Liaocheng, and Tianjin. Chongqing, Chengdu, and Zunyi are in south China, whereas Liaocheng and Tianjin are in north China. Fourth, we did not compare the effect of different numbers of smokers in the three groups (colleagues, friends, and relatives) on smoking pregnant women in this study because calculating the number of smokers in the three groups is very difficult.

Conclusions
Most of smoking women quit smoking after they became pregnant. Tailored intervention program to reduce smoking in pregnant women should focus on pregnant women with higher education level, from rural areas, and whose mothers-in-law smoke. Health education workers need to consider these factors fully in future planning to help pregnant women smokers quit smoking. These findings have implications for the WHO recommendations on prevention and management of tobacco use in pregnancy, especially for China.
