MACROSCOPIC STRESS-STRAIN RESPONSE AND STRAIN LOCALIZATION BEHAVIOR OF

BIOPOLYMER-TREATED SOIL

Antonio Soldo¹, Marta Miletić², Victor Aguilar³

ABSTRACT

Enhancement of soil engineering properties with biopolymers has been shown recently as a viable and environmentally-benign alternative to cement and chemical stabilization. Interest in biopolymer-treated soil is evident from the upsurge of related research activities in the last five years, most of which have been of experimental nature. However, biopolymers have not yet found their way into engineering practice. One of the reasons for this may be the absence of computational models that would allow engineers to incorporate biopolymer-treated soil into their designs. Therefore, the main goal of this study is to numerically capture a macroscopic stress-strain response and investigate the effect of biopolymers on the onset of strain localization. Several diagnostic strain localization analyses were conducted, thus providing strain and stress levels at the onset of strain localization, along with the orientations of the deformation band. Several unconfined compression and triaxial tests on the plain and biopolymer-treated soils were modeled. Results showed that biopolymers significantly improved the mechanical behavior of the soil and affected the onset of strain localization. The numerical results were confirmed by the digital image analysis of the unconfined compression tests. Digital image processing successfully captured high strain concentrations, which tend to occur close to the peak stress.

INTRODUCTION

Due to the rapid urbanization of cities and the growth of the human population, soil improvement methods are of increasing importance because of the need to construct on the soft and complicated ground in very adverse and hostile surroundings (Holtz et al. 1981; Hinchee and Smith 1992; Umar et al. 2016; Ashraf et al. 2017). The primary method that is conventionally applied to enhance the engineering properties of the soil is chemical treatment, and one of the most commonly used chemical stabilization agents is cement. Even though it is effective and cost-efficient, cement has several adverse effects on the environment. For instance, it can initiate the formation of the heat islands, contaminate underground water, eradicate vegetation, prevent vegetation growth, etc. However, the most severe environmental impact is the production of carbon dioxide ($CO_2$) during the production of cement. The estimations are that the cement production industry contributes to more than six percent of the world’s $CO_2$ emission in recent years (Andrew 2018). Therefore, the need to replace environmentally-harmful solutions, such as cement, is in high demand.

One of the eco-friendly solutions is microbial induced carbonate precipitation (MICP). MICP is a biological approach that requires the presence of a large microbial community in the coarse-grained soil. The reactions between microorganisms and soil particles create a cementitious bond that improves soil properties. MICP proved to be effective in increasing the strength and load-bearing capacity of the soil (DeJong et al. 2010; Chang et al. 2016; Choi et al. 2016; Umar et al. 2016; Li et al. 2018). However, this approach comes with certain drawbacks. It can result in the generation of effluent ammonia, and it can only be implemented in coarse-grained soil. The reason for the latter is that the pores of the fine-grained soil are very small and hence not suitable for the habitation of microbes (Ashraf et al. 2017).

Another eco-friendly approach for soil stabilization is the utilization of biopolymers. Biopolymers are naturally made polymers extracted from plants, shells, fungi, and yeast. They have been used in the food industry, the cosmetic industry, medicine, and agriculture (Katzbauer 1998;
Lee and Mooney 2012; Gombotz and Wee 2012; Thombare et al. 2016). Since many of them are known as harmless and edible, they can be considered as eco-friendly agents for soil treatment (Chang et al. 2016). Their advantage over the MICP treatment is that they can be used in both fine- and coarse-grained soils, and they do not generate the effluent ammonia (Chang et al. 2015; Aguilar et al. 2016). Up to date, several research studies have shown the positive biopolymer effect on the soil strength improvement, permeability reduction, and soil collapsibility decrease (Chang et al. 2015; Ayledeen et al. 2017; Wiszniewski et al. 2017; Cabalar et al. 2017; Soldo and Miletić 2019; Toufigh and Kianfar 2019; Soldo et al. 2020).

The vast majority of the research on biopolymer-treated soil was experimental in nature. One of the reasons why biopolymer treatment of soil has not found its way into civil engineering practice could be the absence of computational models that would allow engineers to incorporate biopolymer-treated soil into their designs. Some of the research that conducted numerical modeling is by Ayledeen et al. (2017). They created a finite element model to investigate the behavior of the treated collapsible soil after and before water immersing. The treated and untreated soils were simulated by Mohr-Coulomb’s criterion with an associated flow rule. The commercially available finite element software Plaxis 2D was used. The results of the numerical analysis showed the treating soil with a biopolymer would increase the soil bearing capacity and reduce soil settlement during and after saturation. The results of the numerical analysis on untreated soils were in close agreement with the results of the in situ plate load tests.

Another example of numerical modeling of the biopolymer treated soil was presented by Chen et al. (2016). In their experimental and numerical research, surface strength of biopolymer-treated mine tailings, made of finely ground rock, was investigated. They conducted experimental research on the biopolymer effect on the penetration force of a cylindrical penetrometer. In the numerical part of their study, they used the discrete element method to simulate the penetration test on the mine tailings stabilized with biopolymer solutions. Their numerical analysis, which was
conducted in PFC3D v4.0 using the parallel bond model, showed coinciding results with their
experimental analysis. The numerical simulations showed an increase in the tensile and shear
strengths with higher biopolymer concentration, indicating that the higher concentration of
biopolymer causes larger inter-particle bonding.

To the best knowledge of authors, no previous attempts have been made towards conducting a diagnostic strain localization analysis in biopolymer-treated soil. Strain localization is a characteristic of elastic-plastic materials that indicates the onset of narrow deformation bands. It is characterized by a jump in strain rate and is followed by reduction of a load-carrying capacity, which often indicates an imminent failure of the materials and structures. Thus, the main goal of this study was to numerically capture and experimentally validate a macroscopic stress-strain response and predict the onset of strain localization in elastic-plastic biopolymer-treated soil. In particular, this study focused on soil treated with three types of biopolymers that were modeled by the linear Drucker-Prager model. A combined numerical-analytical algorithm that can capture a stress-strain response and inception of strain localization in biopolymer-treated soil was implemented. Actual unconfined compression and unconsolidated undrained tests, which were performed on plain and biopolymer-treated soil, were modeled. The analyses presented herein allowed an improved characterization of the biopolymer effect on the failure initiation by providing stress and strain levels at the onset of strain localization, as well as orientations of the accompanying discontinuities and corresponding strain localization modes. Ultimately, a diagnostic strain localization analyses provided a quantitative measure of biopolymer contribution toward increased resilience and toughness of these important and environmentally friendly materials.

Following the introduction in this section, a detailed description of the experimental program is provided. This is followed by the description of conditions for the onset of discontinuous bifurcations and an application to the Drucker-Prager model. Finally, calibration of
constitutive models, stress-strain responses, and predictions for the onset of strain localization are presented. A summary of major findings is provided at the end.

EXPERIMENTAL RESEARCH

Soil

Two types of sand were used as a base material in this study, silty sand and pure sand. Both sand types were classified following the ASTM D6913-17 and ASTM D4318-17 standards. The silty sand had 39% fine particles with the liquid limit, plastic limit, and the index of plasticity being 49, 29, and 20, respectively. Therefore, according to the Unified Soil Classification System, fine particles were classified as silt with low plasticity, and the overall classification of this soil was SM (silty sand).

The pure sand was obtained from a site close to Destin, Okaloosa County, Florida, USA. It was mostly made of quartz and was highly uniform. Fine particle content was almost non-existent. The coefficient of uniformity and the coefficient of curvature that were calculated from the grain distribution curve were 1.46 and 0.93, respectively. Since the presence of gravel and fine particles was practically non-existent, USCS classifies this sand as SP (poorly graded sand). This type of sand was investigated only for the image processing segment of this research.

Biopolymers

Xanthan gum

Xanthan gum (XG) is a biopolymer created by the fermentation of a carbohydrate-source medium such as glucose. Xanthan gum was named after the bacterium that induces the process of fermentation, Xanthomonas campestris. Xanthan gum is easily dissolved in hot and cold water. Solutions containing Xanthan gum are non-Newtownians with high pseudoplasticity. At the low shearing rate, the xanthan gum chains are in the state of rest and bound by hydrogen bonds. Increasing the shear rate, the bonds are reduced, which leads to lower viscosity. Due to its fast
interaction with water, rapid agitation and mixing are needed to dissolve xanthan gum in water efficiently. The chains of xanthan gum remain stable over wide ranges of pH values. Therefore, it can be successfully implemented in cleaning products as well as acidic food additives (Katzbauer 1998). Other than that, it can be found in the cosmetic industry, agriculture, and oil drilling industry (Katzbauer 1998).

Guar gum

Guar gum (GG) is a biopolymer extracted from *Cyamopsis tetragonoloba* that is commonly known as guar. Unlike the majority of plant-based gums, guar gum does not have any uronic acid in its molecular structure. Also, it has a high molecular weight when compared with other naturally occurring water-soluble polysaccharides. It is worth mentioning that guar gum formations are stable over a broad range of pH. Therefore, it can be dissolved in water. Even small concentrations of guar can significantly increase the viscosity of the solution it is mixed in. Some of its applications can be found in the cosmetic industry, food industry, agriculture, and oil drilling (Thombare et al. 2016).

Beta-glucan

Beta-glucan (BG) is a biopolymer that consists of glucose molecules. It is extracted from the cells of yeast, fungi, some types of bacteria, and certain types of cereals. The molecular structure of beta-glucans depends on the source they were extracted from. Beta-glucans molecules can vary on the kind of linkages, branching, molecular weight, solubility, and polymer charge (Volman et al. 2008). Beta-glucan used in this study was Beta 1.3/1.6 glucan. The extraction process of beta-glucan depends on the parent source and the molecular bonds of the polymer. Therefore, an appropriate solving agent has to be selected. Molecular structures of beta-glucan that are held loosely outside the cells can be extracted with hot water. Beta-glucan molecules that are held tightly to the cell walls can be released by hot alkali. Beta-glucan, in its powder form, can be dissolved in hot and cold
water, which results in forming a gelatinous solution (Bacic et al. 2009). Beta-glucans are heavily investigated in medicine for health improvement (Volman et al. 2008; Bacic et al. 2009).

**Specimen preparation**

All specimens were prepared by dry mixing of biopolymer and silty sand. The biopolymer concentrations that were used were 0, 1, 2, 4% with respect to the mass of the soil, where 0% represents the plain soil with no additives. After the biopolymer was uniformly mixed with soil, water was sprayed up to 16.5% of the soil mass. After the water was homogeneously added to the biopolymer-soil mixture, the biopolymer-soil was compacted in the molds that were intended for the unconfined compression, splitting tensile, and triaxial tests.

The mold for the specimens which were tested for unconfined compression had a diameter of 3.3 cm and a height of 7.1 cm. Additionally, several cube specimens with dimensions of 5x5x5 cm were made to monitor the development of the strain and detect the inception of strain localization during the unconfined compression test by means of digital image correlation. The cube specimens were chosen because of the flat surface of the sides of the cube. Specimens for the triaxial test had a mold with a diameter of 7 cm and a height of 14 cm. Furthermore, specimens for the splitting tensile strength test were made with attention to use them for calibration of the numerical model.

The mold that was used to make the specimens for the splitting tensile strength test had a diameter and height of 3.5 and 1.8 cm, respectively. After preparation, specimens were extruded from the molds and left to cure for five days (specimens for the unconfined compression and splitting tensile test) of time and seven days (specimens for the triaxial test). The reason for different curing time is the fact that the triaxial specimens were larger and required more curing time to achieve their full strength.
**Mechanical testing**

For determination of strength in the unconfined compression test, the axial load was applied with a strain rate of 1.5% /min, as per ASTM D2166. The compressive strength of the specimen was computed by dividing the maximum load attained during the test by the corresponding cross-sectional area of the specimen.

The unconsolidated undrained test was performed in accordance with ASTM D2850-15. The specimens were placed in a plexiglass chamber under the confining pressure of 100 kPa. During the shearing stage of the test, the axial strain was applied under the rate of 0.7 %/min.

Splitting tensile tests were performed following general procedures described in the ASTM D3967-16 but with a modified apparatus to accommodate small specimen sizes and relatively low loads. The load was applied at the constant strain rate of 1.5 %/min. It must be noted that the splitting tensile test does not give direct soil tensile properties. Thus, the tensile strength was back-calculated from the maximum compressive load and the dimension of the specimens using the following formula (Akin and Likos 2017):

\[ \sigma_T = \frac{2P}{\pi LD} \]  

where \( \sigma_T \) is tensile strength; \( P \) is a compressive force at failure; \( D \) is the diameter of the specimen; \( L \) is specimen thickness.

**Digital image acquisition and processing**

The digital image processing technique was used to monitor the development of the strain component and detect the inception of strain localization. The cube specimens were chosen because of the flat surface of the sides of the cube. The flat surface of the cube specimens was appropriate for the image processing software (GOM Correlate) that can record the strain development in pressure-sensitive materials.
Since the quality and accuracy of the image processing rely on a high-contrast random pattern, a distinctive speckle pattern was applied to the surface of the specimen with a colored marker. The digital images of the soil samples were continuously recorded at a constant position (20 cm from the center of the specimen) for image consistency and uniformity. The resolution of the camera was 12 MP, and it was able to capture 30 frames per second.

The image processing software splits the recording as a series of images. The applied pattern is recognized by the software and isolated as a surface of observation. That surface is transformed into a group of pixels. In this study, the surface of interest (45×45 mm) was transformed into approximately 570×570 pixels. The position of each pixel and the distance from the surrounding pixels are tracked through the software. Each picture is compared to the previous one, therefore the software can detect the change of the pixel position. Following that technique, the software can detect and quantify displacement and strains that occur in the initial recording. Furthermore, the unconfined compression apparatus stores timestamps through the test, while the image processing software takes the time steps from the video recording. Therefore, the correlation between the experimental results and the image processing software could be drawn.

**NUMERICAL MODELING**

**Stress-strain relationship**

The biopolymer-treated soil was assumed to be an elastic-plastic material experiencing an infinitesimal strain and obeying a general non-associative flow rule. Normal components of stress and strain tensors are positive in tension herein. The macroscopic stress-strain relationship for plastic loading is given by (Miletić 2016, Miletić and Perić 2018):

\[ \sigma = D\varepsilon - \varepsilon^p \]

(2)
where subscript notation represents the order of the tensor, superscripts indicate elastic (e), plastic (p) or elastic-plastic (ep) component, “•” over a symbol represents “rate” (time derivative).

Therefore, $\dot{\sigma}_{ij}$, $\dot{\epsilon}_{ij}$, and $\dot{\epsilon}_{ij}^p$ are the rates of a second-order Cauchy stress tensor, infinitesimal strain tensor, and infinitesimal plastic strain tensor, respectively. $D_{ijkl}^e$ is the corresponding elastic stiffness moduli tensor of the biopolymer-treated soil, and is given by (Miletić and Perić 2018):

$$D_{ijkl}^e = \mu (\delta_{ik} \delta_{jl} + \delta_{jk} \delta_{il}) + \lambda \delta_{ij} \delta_{kl}$$

(3)

and $\delta_{ij}$ is Kronecker delta, and $\mu$, $\lambda$ are Lamé’s constants of the composite.

The two-invariant yield function ($F$) was used to describe the plastic behavior of a pressure-sensitive cementitious biopolymer-treated soil. It is defined as:

$$F = F(\sigma_{ij}, \kappa)$$

(4)

where $\kappa$ is a plastic hardening variable.

The plastic flow rule and hardening law are respectively given by:

$$\dot{\epsilon}_{ij}^p = \dot{\lambda} \frac{\partial G}{\partial \sigma_{ij}}$$

(5)

and

$$\dot{\kappa} = h(\dot{\epsilon}_{ij}^p) = \dot{\lambda} h \left( \frac{\partial G}{\partial \sigma_{ij}} \right)$$

(6)

where $\dot{\lambda} \geq 0$ is a plastic multiplier, $h(\dot{\epsilon}_{ij}^p)$ is the first order homogeneous generally nonlinear function, and $G$ is a plastic potential function. The non-associated flow rule was used to more realistically model the behavior of treated pressure-sensitive materials such as biopolymer-soils (Hirai et al. 1989; Rahimi et al. 2015).

The plastic multiplier $\dot{\lambda}$ is obtained from the consistency condition in plastic loading, as:

$$\dot{\lambda} = \frac{f_q D_{ijkl}^e \dot{\epsilon}_{ij}}{H + f_q D_{ijkl}^e g_{kl}}$$

(7)
where gradients of a yield function and plastic potential are denoted by $f_{ij}$ and $g_{ij}$, respectively. The actual hardening modulus $H$ is given by:

$$H = -\frac{\partial F}{\partial \kappa} h(g_{ij})$$

(8)

It is positive, negative, or zero for hardening, softening, or perfect plasticity, respectively.

By combining Eqs. (2), (5), and (7), a tangent elastic-plastic stiffness moduli tensor $D_{ijkl}^e$ is obtained as:

$$D_{ijkl}^e = D_{ijkl}^e - \frac{D_{ijmn}^e g_{mn} f_{pr} D_{prkl}^e}{H + \int_{mn} D_{mnpp}^e g_{pr}}.$$  

(9)

The yield function, $F$, and rate of the plastic multiplier satisfy Kuhn-Tucker conditions as follows:

$$\lambda \geq 0, \quad F(\sigma, \kappa) \leq 0, \quad \lambda F(\sigma, \kappa) = 0.$$  

(10)

**Onset of strain localization**

The diagnostic strain localization analysis was performed on the constitutive level. The inception of strain localization may be considered as a bifurcation problem that signifies a loss of stability of the constitutive relation governing a uniform deformation.

It is assumed that the jump in a displacement rate along the singular surface $\Gamma$ is constant, which is expressed as (Miletić and Perić 2018):

$$\left[\dot{u}_i\right]_\Gamma = \left(\dot{u}_i^+ - \dot{u}_i^-\right)_\Gamma = \text{constant}$$

(11)

where $\dot{u}_i^+$ denotes the displacement rate on one side of the $\Gamma$ and $\dot{u}_i^-$ the other side.

Equation (11) generally describes the kinematics of a strong discontinuity. The special case obtained by equalizing the right-hand side of Equation (5.10) to zero represents a weak discontinuity. At this point, no assumptions are made about the homogeneity and variation of $\left[\dot{u}_i\right]$. 

11
in the neighborhood of the singular surface $\Gamma$. Combining Eq. (11) with the kinematical definition of

infinitesimal strain rate gives the following expression for a jump in strain rate across the singular

surface $\Gamma$:

$$\left[ \varepsilon_{ij} \right]_{\Gamma} = \frac{1}{2} \left( z_i n_j + z_j n_i \right)$$  \hspace{1cm} (12)

where $z_i$ is the eigenvector corresponding to the relevant eigenvalue problem, as discussed below,

$n_i$ is the unit vector that is normal to the surface $\Gamma$.

Furthermore, the equilibrium along the singular surface imposes the following condition on

the traction rate ($\dot{t}$):

$$\left[ \dot{t}_{ij} \right]_{\Gamma} = \left( \dot{t}_{ij}^+ - \dot{t}_{ij}^- \right)_{\Gamma} = 0.$$  \hspace{1cm} (13)

Combining Equations (2), (12), and (13) leads to the classical bifurcation criterion (Rudnicki and

Rice 1975) which is, given by:

$$Q_{ik} z_k = n_i D_{ijk} n_j z_k = 0$$  \hspace{1cm} (14)

where $Q_{ik}$ is an acoustic tensor, also known as a characteristic tangent stiffness tensor. Equation

(14) is based on the assumption that a so-called plastic/plastic bifurcation precedes an

elastic/plastic bifurcation. In the former case, the primary and bifurcated incremental fields both

correspond to plastic loading, while in the latter, only one of the incremental fields corresponds to

plastic loading. It was shown (Ottosen and Runesson 1991) that the plastic/plastic bifurcation

always precedes elastic/plastic bifurcation.

In order to solve for the critical amount of hardening necessary for the onset of strain

localization, the following eigenvalue problem was considered:

$$Q_{ik} z_k^{(j)} = \lambda^{(j)} Q_{ik} z_k^{(j)}, \ j=1,2,3$$  \hspace{1cm} (15)

where $(j)$ indicates the direction of principal stresses.
Nontrivial solutions of the eigenvalue problem are possible only when the acoustic tensor $Q_{ik}$ is singular. The first two eigenvalues are elastic and equal to one while the third eigenvalue is plastic, and it was given by Runesson et al. (1991) as:

$$\lambda^{(3)} = 1 - \frac{b_i P^{e}_{ik} a_k}{H + f_{mn} D^{e}_{mnpp} g_{pr}}$$  \hspace{1cm} (16)$$

where $P^{e}$ is the inverse of the elastic acoustic tensor and the vectors $a_i$ and $b_j$ are defined as

$$a_i = f_{mn} D^{e}_{mnij} n_j, \quad b_j = n_i D^{e}_{ijnm} g_{mn}$$  \hspace{1cm} (17)$$

The corresponding eigenvector is given by the following expression:

$$z^{(3)}_i = \kappa P^{e}_{ij} b_j$$  \hspace{1cm} (18)$$

where $\kappa$ is an arbitrary scalar.

By setting $\lambda^{(3)}$ from Equation (16) equal to zero, a hardening modulus $H(n)$ was obtained.

Finally, the critical amount of hardening necessary for the onset of strain localization was obtained by solving the following constrained optimization problem:

$$H_{cr} = \max_{n_i} H(n)$$  \hspace{1cm} where $n_i n_i = 1$  \hspace{1cm} (19)$$

where the right side of the equation above represents the maximization of the function. The corresponding bifurcation angle $\theta$ represents the angle between the minor stress axis and the normal vector $(n_1, 0, n_3)$. It can be determined from the expression:

$$\tan^2 \theta = \frac{n_1^2}{n_3^2}$$  \hspace{1cm} (20)$$

Analytical solutions for $H_{cr}$ and corresponding critical bifurcation angles were given by (Ottosen and Runesson 1991).
The analysis, in this study, was based on the linear Drucker-Prager model and the parameters of the total stress. Yield and plastic potential function were presented as follows:

\[
F = \left( \frac{1}{3} \tan \beta \right) I_1 + \sqrt{J_2} - \kappa
\]

(21)

\[
G = \left( \frac{1}{3} \tan \psi \right) I_1 + \sqrt{J_2}
\]

(22)

Gradients of linear Drucker-Prager yield and plastic potential functions are given by

\[
f_{ij} = \frac{1}{3} \tan \beta \cdot \delta_{ij} + \frac{\sqrt{3}}{2 \sqrt{J_2}} s_{ij}
\]

(23)

\[
g_{ij} = \frac{1}{3} \tan \psi \cdot \delta_{ij} + \frac{\sqrt{3}}{2 \sqrt{J_2}} s_{ij}
\]

(24)

where \( s_{ij} \) is stress deviator tensor; \( \beta \) is internal friction angle; \( \psi \) is dilatancy angle; \( I_1 \) and \( J_2 \) are first and second deviatoric stress invariants, respectively.

After the critical hardening has been obtained, the onset of strain localization can be determined. The onset can be determined by comparing the values of the critical hardening modulus with the actual hardening modulus. The actual hardening modulus \( (H_{\text{act}}) \) is calculated from the response representing the actual stress and plastic strain.

Numerical simulation

The actual stress-strain response was obtained by simulating the samples by a single eight-node element modeled with 3D integration. The unconfined compression tests were conducted by applying a constant vertical strain rate and keeping the principal stresses in the horizontal directions at zero. The unconsolidated undrained tests were performed under a constant vertical strain rate and applying the horizontal pressures following the experimental tests. The inception of
the strain localization will occur at the moment when the actual hardening modulus equalizes with
the critical hardening modulus.

_Calibration of constitutive model_

The Drucker-Prager model was calibrated against the unconfined compression, splitting tensile
strength test, and the unconsolidated undrained tests that were performed on plain and
biopolymer-treated silty sand. The calibration example is presented in Fig. 1.

The experimental data were available for the plain soil and the soil treated with three
biopolymer concentrations (1, 2, and 4%). However, only the data for the soil treated with 0, 1, and
4% was used for the calibration. The data for the soil treated with 2% biopolymers was used for the
validation of the proposed model. The elastic and plastic parameters were predicted from linear
interpolation of the results for the soil with 0, 1, and 4% biopolymers. To achieve the best values of
the input parameters, the least-squares fit was used. The least-squares fit minimizes the relative
error, and it was based on the experimental data.

Young's modulus was obtained for the plain and treated soil from the unconfined
compression tests. The Young's modulus was calculated as the slope of the elastic portion of the
stress-strain response. The calculated values of Young's modulus for the plain and treated soil were
in the range of previously reported values (Truty and Obrzud 2011; Chang et al. 2015). Poisson's
ratio (ν) was kept constant for all biopolymer-treated soil and was selected from the recommended
values for different types of materials (Das 2019).

For the linear Drucker-Prager criterion used in this study, the internal friction angle (β) and
cohesion (d) were taken from the linear yield surface in the p-q stress plane (Figure 5-1). The
cohesion for the samples with 2% of biopolymers was calculated from the predicted friction angle
and the initial stress level of the predicted hardening. The plasticity models for the nonassociated
flow require a value for the dilatation angle (ψ) that was kept constant for all biopolymer-treated
soil and was assumed based on suggested values (Strömblad 2014). Table 1 summarizes the material properties used for the proposed model.

The isotropic non-linear hardening was used in all test simulations and was implemented into the model in a tabular form. The hardening was obtained from the averaged values of the experimental tests (unconfined compression). The plastic strains were calculated by subtracting the elastic strain components from the amount of total strains. Prior to that, the elastic strain components were calculated by dividing the axial stress response with the modulus of elasticity. The example of actual and predicted hardening response for the unconfined compression is presented in Fig. 2. The hardening curve for the silty sand with 2% BG was interpolated from the parameters of the equations fitting the experimental data.

RESULTS

Unconfined compression test

The linear Drucker-Prager model was used to simulate the 3D stress state of the unconfined compression tests. A comparison between the numerically predicted responses and experimentally observed response for the unconfined compression test are presented in Fig. 3 - Fig. 5. The stress-strain responses of specimens with 0, 1, and 4% were used for calibration of the model, while the specimens with 2% were used for validation.

Fig. 3 shows the numerical response (solid line) and experimental data (scatter data) of the unconfined compression test of the BG-treated silty sand. For comparison, the same results of the plain silty sand are shown Fig. 3a). From Fig. 3 it can be seen that the onset of strain localization (OSL) of the silty sand increased with the addition of BG. Furthermore, it can be seen that the peak stress also increased with the biopolymer addition. Fig. 3a, b, and d show a relatively better match between the experimental data and the numerical response when compared with Fig. 3c. That is because of the numerical response in Fig. 3a, b, and d was based on the calibrated material
properties, whereas the numerical response in Fig. 3c was obtained from the predicted material properties. The predicted model could not detect the OSL for the silty sand treated with 4% BG because the actual critical hardening never equalized with the calculated critical hardening.

In Fig. 4, the numerical response and experimental data of the unconfined compression test of the GG-treated silty sand can be seen. Additionally, the experimental and numerical results of the treated silty sand were compared with the results of the plain silty sand (Fig. 4a). It can be seen that the peak stress increased with the increase of the GG concentration.

Fig. 4 shows that the OSL of the silty sand increased with the addition of GG. The exception is the concentration of 1% GG (Fig. 4b). Even though the peak stress of the silty sand increased with the addition of 1% GG, the OSL occurred at the lower strain level for 1% GG. The reason behind that is that the onset of strain localization depended on the yield stress and the peak stress, but it was primarily governed by the hardening response. Furthermore, the numerical response of the silty sand with 2% GG shows a relatively good match with the experimental data (Fig. 4c).

Fig. 5 shows the experimental data and the numerical response of the unconfined compression test of the XG-treated silty sand. The same results of the silty sand are shown in Fig. 5a. Fig. 5 shows that the OSL of the silty sand was postponed with the addition of XG. Additionally, it can be seen that the peak stress also increases with the increase of XG. The numerical response of the silty sand treated with 2% XG showed a relatively good correspondence with the experimental data even though it was based on the predicted material properties. The predicted model could not detect the OSL for the silty sand treated with 4% XG because the actual critical hardening did not raise to the level of the calculated critical hardening.

Fig. 6 summarizes the level of the total axial strain (Fig. 6a) and the axial stress at the OSL (Fig. 6b). It is evident that the stress at OSL increased with the increase of biopolymer concentration, and that the level of total strain increased for most of the biopolymer concentrations.
The bifurcation angle is represented by the angle between the minor stress axis ($x_3$) and the unit vector ($n$) that lays in the $x_1$, $x_3$ plane (Ottosen and Runesson 1991). From Fig. 7, it can be seen that the addition of the biopolymers altered the bifurcation angle. In particular, the results show that the bifurcation angle kept increasing with the increase of the GG and BG concentrations. For the XG-treated soil, the highest bifurcation angle was achieved for the concentration of 1%, and it kept decreasing with the increase of XG concentration. That phenomenon can be related to the increase in the ductility of the material with the increase of the XG concentration. However, in all cases of the treated soil, the bifurcation angle was higher than the bifurcation angle of the plain soil. In general, the increase of the bifurcation angle results in a steeper deformation bend that changes the failure behavior.

**Unconsolidated-undrained triaxial test**

The linear Drucker-Prager model was also used to simulate the 3D stress state of the unconsolidated-undrained triaxial test. The experimental stress-strain response was compared with the numerical response. The onset of strain localization was considered when the actual hardening equalized with the critical hardening. The results were summarized in Fig. 8. The level of the stress at OSL increased with the increase of the biopolymer concentration (Fig. 8a). However, Fig. 8 shows a trend of the decreasing level of strain at OSL with the increase of biopolymer concentration. The reason for that behavior is the fact that the onset of strain localization depends on the yield stress and the hardening response. These results indicate that the biopolymer-treated soil had a more brittle behavior than the plain soil at the higher confining pressures.

The change in the bifurcation angle of triaxial specimens (Fig. 8c) showed a similar response, as seen in the unconfined compression test. For all biopolymer types and biopolymer concentrations, the treated soil had a higher bifurcation angle than the plain soil. Additionally, the bifurcation angle kept increasing with the concentration increase of GG and BG. For the XG-treated
soil, the highest bifurcation angle was achieved for the concentration of 1%, and it kept decreasing for the higher concentrations of XG.

Fig. 9 compares the stress-strain responses of the unconfined compression tests and the triaxial tests of the silty sand. As described previously, the onset of strain localization occurs close to the peak of stress-strain curves. Comparing the peaks of the unconfined compression and triaxial test curves, it can be observed that the peaks occur at a higher stress-strain level for the triaxial tests. The reason for that is the applied confinement pressure in the triaxial test. Schnaid et al. (2001) demonstrated that the increase in confinement pressure increases the level of the peak stress in the cemented sand and it postpones the level of strain at which it occurs. Furthermore, the peak stress tends to increase with the increase of biopolymer concentration. Observing only the results of the unconfined compression tests, represented with scattered data, it can be seen that biopolymers tend to increase the level of the peak stress and the level of strain at the peak (represented by the arrow in Fig. 9). The triaxial test results, represented by solid lines, also show that the level of the peak stress increases with the addition of biopolymers. However, the peak occurs at the lower strain level for the treated silty sand than for the plain silty sand. Furthermore, the level of strain tends to decrease with the increase of biopolymer concentration (represented by the arrow in Fig. 9). Similar results were demonstrated in previous research of the stabilized soil (Schnaid et al. 2001; Kutanaei and Choobbasti 2016). That phenomenon is likely related to the ductility of the specimens. The plain soil in the triaxial test demonstrates a more ductile behavior than the treated specimens. Cemented soil can have an abrupt post-peak failure in the triaxial test (Tagliaferri et al. 2011) that indicates the brittleness of the treated soil. It is also more prominent in the sand with no or a small amount of fine particles.
Fig. 10 and Fig. 11 combine experimental response, numerical response, and image processing results for clean sand, and silty sand, respectively. The experimental responses of the unconfined compression tests were presented by markers in Fig. 10 and Fig. 11. The solid dark and red lines represent the numerically obtained stress-strain curve, and OSL, respectively.

The heat maps in Fig. 10 and Fig. 11 are presented as overlays on the soil surface and show the strain concentration and strain propagation on cube samples. Three heat maps represent three different timestamps when the heat map was generated. The first image represents the early stage of the unconfined compression with no visible strain localization. The second image corresponds to the OSL from the analytical-numerical algorithm. The third image represents the post-peak strain propagation. The arrows in the figures represent the stress-strain level at which the heat map was captured.

Fig. 10a represents the sand treated with 0.5% XG, whereas Fig. 10b represents the sand treated with 1% XG. Comparing the onset of strain localization in the sands with different XG concentrations, it can be seen that OSL occurs for almost the same strain level, in fact, moderately lower for the sand with 1% XG. However, the peak stress reached was higher for the specimen treated with 1% XG. Shortly after reaching the peak stress, the stress drops more abruptly for the specimen with 1% XG because of the increased brittleness.

The heat maps in Fig. 10a and Fig. 10b show the process of strain concentration for the sand specimen. In both figures, in the early stages of the test, the strain distribution is uniform along the whole surface. While approaching the red line (OSL), the strains start to concentrate in one deformation plane. The third heat map image shows the propagation of the deformation plane with the increase in strain after the OSL has been reached. Additionally, the heat map shows the created bifurcation angle as the result of the strain localization. The bifurcation angle of sand with 0.5% XG was calculated as 65°, while the bifurcation angle of sand with 1% XG was 75°. It can be concluded
that the increase of biopolymer concentration can increase the bifurcation angle of sand. A similar
trend was previously reported for the biopolymer-treated silty sand where the bifurcation angle
was found through the analytical-numerical algorithm.

Observing Fig. 11, a combined experimental response, numerical response and image
processing results for silty sand can be seen. Fig. 11a represents the plain silty sand, Fig. 11b
represents the silty sand treated with 0.5% XG, and Fig. 11c shows the silty sand with 1% GG. Even
though the peak stress increased with the addition of biopolymers, the strain level for the OSL did
not significantly change. This indicates that higher concentrations of XG and GG are required to
postpone the OSL of the silty sand.

The heat maps in Fig. 11a, Fig. 11b, and Fig. 11c show the process of strain concentration for
the biopolymer-treated silty sand. In all three figures, in the early stages of the test, the strain
distribution is uniform along the specimens’ surfaces. While approaching the OSL, the strains start
to concentrate on one deformation plane. The second image shows the high strain concentration at
the moment of the OSL which was determined from the analytical-numerical algorithm. The third
heat map image shows the strain propagation that occurs after the OSL. Additionally, the heat maps
show the created bifurcation angle due to the strain concentration. The bifurcation angle of the
biopolymer treated soil shows higher values for the biopolymer-treated silty sand. The plain silty
sand (Fig. 11a) had the bifurcation angle of 55°. The silty sand with 0.5% XG (Fig. 11b) had the
bifurcation angle of 60°, while the concentration of 1% GG (Fig. 11b) resulted in the bifurcation
angle of 70°. As reported previously in this study, the bifurcation angle of the silty sand increased
with the addition of biopolymers. The difference between the second heat map image (at the OSL),
and the third image (after the OSL) was more prominent in the sand than in the silty sand. The
reason for that is the difference in the nature of the base material. The treated sand had a more
brittle response than the treated sand wilt. Furthermore, the break of the treated sand was cleaner,
whereas the failure of the silty sand resulted in the partial crumbling of the material. Therefore, the nature of the treated sand was more suitable to observe under the image processing software.

Observing the unconfined compression test under an image processing software showed high strain concentrations at the moment of the OSL. However, there are some drawbacks that should be considered. The image acquisition with a single camera and subsequent processing gave a 2D output only on one side of the specimen. However, during the actual 3D test, it is unknown on which specimen side will the deformation band occur. Therefore, the digitally obtained deformation planes for the tested specimens might not be the most critical ones. To solve these issues, multiple cameras facing each specimen side should be used.

CONCLUSIONS

The main objective of this research was to perform the computational and experimental diagnostic strain localization analyses in biopolymer-treated soil. Two types of soil (silty sand and clean sand) were investigated together with the three types of biopolymers (xanthan gum, guar gum, and beta-glucan). A numerical-analytical algorithm was implemented to capture the stress-strain response and the inception of the strain localization. The experimental data were collected for the plain silty sand and silty sand with 1, 2, and 4% biopolymer concentrations. Three tests used for the calibration purposes were unconfined compression, unconsolidated undrained triaxial, and splitting tensile strength tests. However, the experimental data of the silty sand with 2% biopolymers was not used for the calibration, but only for validation purposes.

The stress-strain response of the specimens subjected to uniaxial compression and triaxial stress states were simulated. In addition, the inception of the strain localization was calculated for each specimen and each stress state. For the unconfined compression test, it was found that the OSL was postponed for most concentrations of biopolymers. The peak stress in each test increased with the increase of biopolymer concentration, and OSL always occurred close to the level of the peak
stress. The level of the bifurcation angle of the silty sand increased for all biopolymer concentrations. It was noticed that the increase of GG and BG concentration increases the bifurcation angle. However, for XG, the highest bifurcation angle was noticed for 1% XG, and it kept decreasing for higher concentrations.

The unconsolidated undrained triaxial test showed an increase in the peak stress of the silty sand for all biopolymer concentrations. Also, the increase in the bifurcation angle was noticed for all biopolymer concentrations. The same trend as in the unconfined compression test was noticed. The increase of GG and BG concentrations lead to an increase in the of the bifurcation angle. The highest achieved bifurcation angle for XG treated silty sand was achieved at 1% XG. For higher concentrations, the bifurcation angle started decreasing. However, it was noticed that for the triaxial state of stress, OSL occurred close to the peak stress, and it was advanced for every tested biopolymer concentration.

Several cube specimens, made of silty sand and pure sand, were prepared and tested for the unconfined compression accompanied by image processing. The surface of the cube specimens was marked in a recognizable pattern before the testing. The testing process was recorded and observed in an image processing software GOM Correlate. The strain development was tracked and compared with calculated OSL. OSL appeared close to the peak stress, at which moment the image processing software reported the initiation of the high strain concentrations. To capture more precise strain distribution and bifurcation angles with the image processing software, a 3D image acquisition and analysis should be performed. That approach requires more equipment and will be utilized in future research.

In conclusion, the diagnostic strain analysis shows that the presence of biopolymers in the soil can influence the onset of strain localization. Depending on the stress state, soil type, biopolymer type, and concentration, the strain localization can be postponed or advanced. Analyzing the complex mechanics of biopolymer-treated soil helps to understand the strength
limitations of biopolymer treated soil. Understanding how biopolymers affect the strain localization and failure of soil materials can lead to their utilization in engineering practice.
