Subcellular Investigation of Photosynthesis-Driven Carbon Assimilation in the Symbiotic Reef Coral *Pocillopora damicornis*

Christophe Kopp, Isabelle Domart-Coulon, Stephane Escrig, Bruno M. Humbel, Michel Hignette, Anders Meibom

ABSTRACT  Reef-building corals form essential, mutualistic endosymbiotic associations with photosynthetic *Symbiodinium* dinoflagellates, providing their animal host partner with photosynthetically derived nutrients that allow the coral to thrive in oligotrophic waters. However, little is known about the dynamics of these nutritional interactions at the (sub)cellular level. Here, we visualize with submicrometer spatial resolution the carbon and nitrogen fluxes in the intact coral-dinoflagellate association from the reef coral *Pocillopora damicornis* by combining nanoscale secondary ion mass spectrometry (NanoSIMS) and transmission electron microscopy with pulse-chase isotopic labeling using [13C]bicarbonate and [15N]nitrate. This allows us to observe that (i) through light-driven photosynthesis, dinoflagellates rapidly assimilate inorganic bicarbonate and nitrate, temporarily storing carbon within lipid droplets and starch granules for remobilization in nighttime, along with carbon and nitrogen incorporation into other subcellular compartments for dinoflagellate growth and maintenance, (ii) carbon-containing photosynthates are translocated to all four coral tissue layers, where they accumulate after only 15 min in coral lipid droplets from the oral gastroderm and within 6 h in glycogen granules from the oral epiderm, and (iii) the translocation of nitrogen-containing photosynthates is delayed by 3 h.

IMPORANCE  Our results provide detailed in situ subcellular visualization of the fate of photosynthesis-derived carbon and nitrogen in the coral-dinoflagellate endosymbiosis. We directly demonstrate that lipid droplets and glycogen granules in the coral tissue are sinks for translocated carbon photosynthates by dinoflagellates and confirm their key role in the trophic interactions within the coral-dinoflagellate association.

Photosynthesis plays a central role in many aquatic animals symbiotically associated with microalgae or cyanobacteria (1). Shallow-water reef-building scleractinian corals hosting photosynthetic dinoflagellates of the genus *Symbiodinium* (“zooxanthellae”) represent an emblematic example of such a stable mutualistic endosymbiotic relationship, which is critical for the development and health of coastal coral reef ecosystems in (sub)tropical oceans. The dinoflagellate endosymbionts, located within the coral gastrodermal cells (see Fig. S1 in the supplemental material), significantly contribute to the nutrition of their animal host partner by transferring a large fraction (up to 90%) of their photosynthetically assimilated carbon (C) and nitrogen (N) to the coral in nutrient-poor marine environments (2, 3). These photosynthates are produced by dinoflagellates through the fixation of dissolved inorganic carbon (DIC) via the Calvin-Benson “C3” photosynthetic pathway (4) and through the photosynthesis-dependent acquisition of dissolved inorganic nitrogen (DIN), ultimately via the glutamine synthetase-glutamate synthase (GS-GOGAT) enzymatic cycle (5, 6). The nature of translocated photosynthates (“mobile compounds”) ranges from soluble low-molecular-weight compounds, such as glyceraldehyde, glucose, amino acids, and organic acids (7–9), to more complex molecules, such as free fatty acids (10) or glycoconjutagates (11). However, the detailed pathway of this nutritional autotrophic flux from the dinoflagellate endosymbionts to the different cellular layers composing the coral host tissue, as well as the precise fate and turnover of photosynthates in the symbiotic system, remain poorly documented at the (sub)cellular level.

Symbiotic reef-building corals are regarded as “fat organisms” because they contain 9 to 47% (dry weight) lipids in their tissue, mostly in the form of neutral lipids (triglycerides, wax esters, and sterols) packed into lipid droplets (LDs), which are hypothesized to be a main sink for C-rich photosynthates translocated by dinoflagellates to the coral tissue (12–15). In support of this view, most previous bulk-level studies using radioactive (14C) or stable (15N) isotope labeling found preferential incorporation of translocated photosynthates into a chemically extracted lipid fraction, as well as structural polymeric compounds such as proteins (16–21). Additionally, recent observations indicate morphological and com-
positioned changes of coral LDs upon coral bleaching (i.e., loss of dinoflagellates or their pigmentation) and a positive correlation between abundance of coral LDs and dinoflagellate density or light intensity (22, 23). Nevertheless, despite their supposed key role in the trophic interactions within the coral–dinoflagellate endosymbiosis, a direct demonstration that coral LD biosynthesis is linked with the release of photosynthates by dinoflagellates is still lacking.

Glycogen is another potentially important C reserve pool in the endosymbiosis, previously detected in stony corals both biochemically and ultrastructurally (24, 25). Gene expression for glycogen synthase and glycogen phosphorylase enzymes, which regulate the production and mobilization of glycogen stores, was detected in the reef coral Acropora aspera transcriptome (26). However, the possible incorporation of photosynthates such as glucose (9) into coral glycogen has not been investigated. Furthermore, little attention has been paid to the allocation and turnover of photosynthates within the dinoflagellate subcellular compartments, especially in their C storage structures, which are LDs and starch granules (27, 28).

Nanoscale secondary ion mass spectrometry (NanoSIMS) ion microprobe imaging is a powerful tool to simultaneously image and quantify the distribution and turnover of stable isotopic tracers (e.g., 13C and 15N) inside cells, especially when correlated with ultrastructural transmission electron microscopy (TEM) imaging (29–33). Here, we used this methodological approach on microcolonies (nubbins) of the common Indo-Pacific symbiotic reef-building coral Pocillopora damicornis, which were pulse-labeled in an aquarium for 6 h simultaneously with [14C]bicarbonate and [15N]nitrate ([15NO3]−), followed by an extended chase of 186 h under either normal light/dark cycling (12 h/12 h) or prolonged darkness. We used [15N]nitrate to unambiguously track the flow of N in the endosymbiotic system because nitrate is assimilated by the dinoflagellates only, in contrast to ammonium, the preferred source of DIN for most reef corals, which is simultaneously assimilated by both the dinoflagellates and coral cells (32, 33).

The two main objectives of this study were to visualize and measure in situ, with subcellular resolution, the photosynthesis-dependent incorporation, fate, and turnover of inorganic C in the dinoflagellate endosymbionts and to track the translocation of dinoflagellate photosynthates toward the coral host tissue layers (see Fig. S1 in the supplemental material), especially their incorporation and turnover in coral LDs and glycogen granules.

RESULTS

Assimilation and turnover of carbon and nitrogen in dinoflagellates. NanoSIMS 13C/12C and 15N/14N isotopic images of dinoflagellate endosymbionts indicate spatially heterogeneous intracellular distribution of 13C and 15N incorporated during the 6-h labeling pulse under light (a representative dinoflagellate cell is illustrated in Fig. 1A to C). Regarding incorporated 13C, preferential accumulation was systematically recorded on isotopic images in the following dinoflagellate compartments, identified on corresponding ultrastructural TEM micrographs and collectively termed “C reserves”: (i) large, “primary” starch granules (nomenclature of Doyle and Doyle [27]) forming a cap around the plastidial pyrenoid (red arrows in Fig. 1A and B), (ii) small “secondary” starch granules distributed in the cytosol (blue arrows in Fig. 1A and B), and (iii) highly osmiophilic electron-dense LDs (green arrows in Fig. 1A and B).

NanoSIMS isotopic measurements from regions of interest (ROIs) defined in the dinoflagellate population (as illustrated in Fig. S2 in the supplemental material) show that the average 13C enrichment of the dinoflagellate C reserves increased rapidly, after 15 min, during the 6-h labeling pulse under light, but then it declined by ~80% of its peak value, during the first 18 h of the chase under light/dark cycling, over a period that includes the first 12-h dark phase (Fig. 1D). (Summary data tables and P values from statistical analyses are provided in Data Set S1 in the supplemental material). In parallel, incorporated 13C started to accumulate after 15 min into the pulse in the various other dinoflagellate compartments (e.g., nucleus and plastid) (Fig. 1A, B, and E). In contrast to C reserves, the 13C enrichment of other compartments in the dinoflagellates only slowly decreased throughout the 186-h chase period, by about 60% of its peak value (Fig. 1E; see Data Set S1).

Regarding 15N incorporated by the endosymbionts, this tracer was detected to accumulate in the dinoflagellate C reserves after 30 min into the pulse of labeling, but the 15N enrichment in these compartments remained essentially stable during the chase (Fig. 1D). In the various other dinoflagellate compartments, 15N was incorporated after 15 min into the pulse with a pattern of isotopic depletion throughout the chase almost identical to that of 13C (Fig. 1E). Note that preferential incorporation of 15N into vesicles containing uric acid crystals was confirmed (33, 34) (black arrows in Fig. 1A and C). Figure S3 in the supplemental material illustrates the turnover of both C and N during the pulse-chase experiment in representative dinoflagellates.

In corals maintained for 186 h in constant darkness, following the 6-h labeling pulse under light, the pattern of rapid 13C decrease in the C reserves of dinoflagellates was confirmed (see Fig. S4 in the supplemental material). In addition, the observed ultrastructural changes indicate that both dinoflagellate LDs and starch granules were progressively depleted in the absence of photosynthetic carbon replenishment, an observation concomitant with the gradual appearance of ultrastructural symptoms of dinoflagellate cell degeneration (see Fig. S4). Severe paling of coral microcolonies was also noticed after this prolonged dark treatment (8 days), strongly suggesting that coral bleaching had occurred.

No significant incorporation of 13C and 15N was observed in dinoflagellate and coral cells pulse-labeled for 6 h in darkness following a 24-h pretreatment in darkness (see Fig. S5 in the supplemental material). This result confirms that C and N assimilation by dinoflagellates is light dependent (i.e., related to photosynthesis) and that the contribution of nonphotosynthetic “heterotrophic” C fixation by carboxylation reactions was negligible in both dinoflagellate and coral cells.

Translocation of carbon and nitrogen to the coral host tissue. At the overall coral tissue level, NanoSIMS isotopic measurements from ROIs (as illustrated in Fig. S2 in the supplemental material) demonstrate the gradual translocation of 13C from the dinoflagellate endosymbionts to all four coral epithelia, starting after only 15 min and stabilizing after 48 h in the pulse-chase experiment with light/dark cycling (Fig. 2A, B, and D). (Summary data tables and P values of statistical analyses are given in Data Set S1 in the supplemental material, and Fig. S6 in the supplemental material illustrates a sequence of representative TEM and NanoSIMS isotopic images of the coral oral tissue.) Among the coral tissue layers, 13C-labeled photosynthates transferred by dinoflagellates during the pulse were observed to rapidly (within 15 min) accumulate
in the coral LDs from the oral gastroderm. In contrast, incorporation into coral LDs from the three other epithelia was much less efficient and occurred with a 3-h delay (Fig. 2A, B, and E; see Data Set S1 and Fig. S6). In the 186-h chase, coral LDs from the oral gastroderm were then strongly depleted in $^{13}$C, with more than a 90% decrease in average $^{13}$C enrichment compared to the peak value at the end of the pulse (Fig. 2E). Note the very high level of variability in $^{13}$C enrichments among individual coral LDs from the oral gastroderm, especially after 6 h into the pulse (Fig. 2E).

At the end of the 6-h pulse, $^{13}$C-labeled photosynthates translocated by dinoflagellates were also systematically found associated with numerous ~50-nm-diameter glycogen granules, located in the apical region of coral cells from the oral epiderm (Fig. 3). (An enlarged view of Fig. 3D is provided in Fig. S7 in the supplemental material.) In these areas rich in glycogen granules, the $^{13}$C labeling was found from NanoSIMS line profiles to gradually decrease over the 186-h chase under light/dark cycling, reaching ~85% $^{13}$C depletion compared to the peak value at the end of the pulse (see Fig. S8 in the supplemental material).

Translocation by dinoflagellates of $^{15}$N-labeled photosynthates to the coral tissue (overall coral cells) was recorded starting after 3 h into the pulse—i.e., with a much longer delay in comparison to $^{13}$C (Fig. 2D). Moreover, in contrast to translocated $^{13}$C, the spatial distribution of translocated $^{15}$N was found to be relatively homogeneous in coral cells, with no specific subcellular compartments in the host tissue benefitting preferentially from the dinoflagellate supply of $^{15}$N-labeled materials (Fig. 2A and C; see Fig. S6 in the supplemental material). Major spatial patterns and temporal time scales of $^{13}$C and $^{15}$N fluxes in the symbiosis are summarized in Table 1.

**DISCUSSION**

Subcellular imaging of photosynthetic C and N assimilation and utilization by the dinoflagellate endosymbionts. This study demonstrates that in the tropical reef-building coral *P. damicornis*, a substantial fraction of photosynthetically assimilated inorganic C and N was retained in the dinoflagellate cells during the pulse-chase experiments. C-containing photosynthates rapidly (within ~15 min) accumulated into dinoflagellate lipid droplets (LDs) and starch granules (both primary and secondary), with subsequent rapid turnover. Most accumulated $^{13}$C was depleted from dinoflagellate C reserves within the first 18 h of the chase under light/dark cycling, over a period that includes the first 12-h dark phase. This result strongly suggests a diurnal rhythmicity in the formation (under light) and utilization (under dark) of LDs and starches by dinoflagellates. The $^{15}$N labeling observed in the $^{13}$C-enriched di-
noflagellate LDs and starch granules most likely reflects the incorporation of 15N-labeled proteins, possibly enzymes involved in the synthesis and further catabolism of neutral lipids or carbohydrates, onto the surface or into the internal matrix of these compartments (35, 36). In addition, assimilated 13C and 15N were allocated to the various other dinoflagellate compartments (including, e.g., the nucleus and plastid), albeit for C with a lower efficiency and a slower turnover than for the C reserves, most likely reflecting the utilization of C and N for dinoflagellate maintenance, growth, and division.

These NanoSIMS results obtained in situ (i.e., in the intact coral-dinoflagellate association) are in agreement with data from previous bulk-level isotopic incubation analyses with 14C- or 13C-labeled bicarbonate, which report a rapid loss of 14C or 13C enrichment in the dinoflagellate fraction within the first hours of the chase, especially during the first night (17, 21, 37–39). In particular, by labeling the reef coral Acropora pulchra simultaneously with [13C]bicarbonate and [15N]nitrate, Tanaka et al. (21) found a dramatic nighttime decrease in the C:N ratio of light-produced compounds, suggesting rapid consumption of photosynthates with high C content (i.e., lipids and carbohydrates) by dinoflagellate respiration. Conversely, in Stylophora pistillata colonies, the rapid decrease in 14C or 13C labeling of the dinoflagellate fraction, observed over a chase period of 24 to 48 h, was mainly ascribed to delayed translocation of 14C- or 13C-labeled photosynthates to the coral host partner (17, 39).

Here, we observed that the rapid 13C decrease in dinoflagellate endosymbionts of P. damicornis is occurring via isotopic depletion of their intracellular LDs and starch granules and not through depletion of their other cell compartments. This result supports the hypothesis that lipids and carbohydrates stored by dinoflagellates during daytime are quickly remobilized, especially during nighttime, via mitochondrial respiration (releasing 13CO2) to sustain dinoflagellate metabolism. Nevertheless, the following additional mechanisms for such rapid 13C depletion in dinoflagellate C reserves cannot be excluded: (i) the effect of an isotopic dilution due to the additional storage of newly produced [12C]photosynthates during the light periods of the chase, (ii) the translocation of 13C-labeled compounds toward the coral host tissue (during light and dark periods of the chase), and/or (iii) the remobilization of stored 13C as building blocks for dinoflagellate maintenance, growth, and division.

Interestingly, by maintaining P. damicornis microcolonies under constant darkness, a treatment known to trigger coral bleaching after about 4 days (40, 41), the ultrastructural disappearance of dinoflagellate LDs and starch granules was systematically accompanied by features of cell vacuolization and damage of organelles, indicative of in situ degradation of the endosymbionts. These observations are additional evidence that photosynthates stored in dinoflagellates under light are essential to further sustain their respiration and metabolism, especially during nighttime.

In marine microalgae, photosynthates produced and stored...
under light might provide C skeletons and energy to support DIN (ammonium and nitrate) uptake and assimilation in the dark (42). The existence of an internal C reservoir in dinoflagellate endosymbionts, metabolized during nighttime to sustain N acquisition, is suggested by the extended time of darkness (at least 15 h) needed to efficiently inhibit ammonium incorporation in symbiotic reef corals (5, 33). Similarly, we demonstrate that prolonged dark pretreatment (24 h) fully repressed nitrate assimilation in dinoflagellates of the reef coral *P. damicornis*. Interestingly, in coastal marine environments, migrating free-living dinoflagellates reach the illuminated sea surface, poor in DIN, during the day, to accumulate excess photosynthates not channeled toward protein synthesis, whereas they descend during the night to a depth enriched in nitrate, which is then efficiently assimilated through the remobilization of light-produced C reserves (43). Hence, the storage of lipids and carbohydrates by dinoflagellates during daytime might constitute a C reserve helping reef corals to efficiently sustain DIN acquisition during nighttime, representing an adaption to nutrient-poor environments.

**The fate of C and N translocated to the coral host.** The present study reveals the subcellular pathways of photosynthetic C translocation from the dinoflagellate cells toward all four epithelia composing the coral host tissue, extending our previous NanoSIMS observations of transepithelial movements of nitrogenous compounds translocated by the endosymbionts (32, 33). In early autoradiographic investigations, transepithelial metabolite fluxes

| TABLE 1 Summary of the main events and time scales traced in this study |
|----------------------|--------------------------------------------------|------------------|
| Symbiotic partner    | Major event traced                               | Time scale       |
| Dinoflagellates      | Photosynthesis-dependent assimilation of bicarbonate and nitrate | 15 min           |
|                      | C allocation to C reserves (lipid droplets and starch) | 15 min           |
|                      | C turnover in C reserves related to diurnal light cycle | ~80% 13C depletion in 18 h |
|                      | C and N turnover in other compartments            | ~60% 13C and 15N depletion in 186 h |
| Coral                | C translocation by dinoflagellates                | 3 h              |
|                      | N translocation by dinoflagellates                | 15 min           |
|                      | Allocation of translocated C to lipid droplets (oral gastroderm) | 15 min           |
|                      | Allocation of translocated C to glycogen (oral epiderm) | 6 h              |
|                      | C turnover in lipid droplets (oral gastroderm)    | ~90% 13C depletion in 186 h |
|                      | C turnover in glycogen (oral epiderm)             | ~85% 13C depletion in 186 h |
have been reported in marine cnidian tissue, albeit at light microscopy level in thick histological sections (44, 45). Moreover, using bulk-level isotopic measurements of separated fractions of dinoflagellate-containing oral gastroderm and dinoflagellate-free oral epiderm prepared from tentacles of a sea anemone, Trench (18) previously found that 18 to 31% of total net photosynthates moved toward the oral epiderm within 10 h of labeling in light with [14C]bicarbonate.

Here, we observed that coral LDs from the oral gastroderm epithelium constitute a major accumulation site for translocated photosynthetically derived 13C, providing direct validation of previous hypotheses (12, 13, 15, 22, 23). The rapid C translocation toward gastrodermal coral LDs, which we visualized already at 15 min from the onset of the pulse, is consistent with results from bulk-level isotopic investigations of symbiotic sea anemones, which reported rapid translocation of photosynthates to the host fraction, within a few minutes following their production (9, 46, 47). Interestingly, we frequently observed 13C-enriched LD-like structures located in the symbiosomal space between the dinoflagellate endosymbiont and the coral gastrodermal host cell (white arrows in Fig. S3 in the supplemental material). These structures have previously been interpreted as “extra-algal” LDs produced by dinoflagellates, in the process of exocytosis toward the host gastrodermal cells (48, 49). However, ultrastructural evidence for such a potential exocytotic process is still lacking. Moreover, the occurrence of LDs within coral cells of dinoflagellate-free epithelia (oral epiderm and calicoderm) implies the existence of other, still unknown, mechanisms of coral LD formation.

This study also provides evidence that coral glycogen granules in the coral oral tissue constitute another major sink for 13C-photosynthates translocated by dinoflagellates. In bulk isotopic analyses of sea anemones, glucose was found to be a major metabolite translocated within minutes from the dinoflagellate endosymbiont to the host fraction (7–9). Moreover, transcriptome analyses have revealed that acroporid (Acropora genus) corals have the enzymatic machinery for synthesis and remobilization of glycogen from and to glucose (26). Consistent with these reports, combined TEM and NanoSIMS observations show incorporation (within 6 h) of external [13C6]glucose (30 μM) into glycogen granules of the coral oral epidermal cells (see Fig. S9 in the supplemental material). Thus, our results provide direct evidence of the functional mechanisms of storage of photosynthetic C, translocated by the dinoflagellate endosymbionts (probably in the form of glucose) to coral glycogen in the oral tissue.

Similar to dinoflagellate C reserves, the 13C depletion observed for coral LDs in the oral gastroderm and for the glycogen granules in the oral tissue most likely reflects the breakdown of neutral lipids and carbohydrates to sustain coral cell respiration. Nevertheless, we cannot exclude the potential contribution of (i) an isotopic dilution effect resulting from the translocation of photosynthates with normal C isotopic composition to coral LDs and glycogen and (ii) the reallocation of stored C toward coral cell maintenance, growth, and division.

Translocation of N-containing compounds by dinoflagellates was not recorded immediately in the coral host partner but was observed with a delay of 3 h following the onset of the pulse-chase experiment under light/dark cycling, confirming previous observations (33). These results suggest a temporal separation between the translocation by dinoflagellates of C- and N-containing photosynthetic assimilates. Compounds bearing C are released within a few minutes after their production, compared to a time scale of hours for N-bearing compounds (summarized in Table 1). It is also possible that early translocation of N to the coral tissue has been partly masked by a potentially high rate of N recycling by the dinoflagellates (5) or by extraction of low-molecular-weight soluble nitrogenous compounds (e.g., free amino acids) during sample preparation. Alternative NanoSIMS sample preparation methods (e.g., cryofixation and cryosubstitution) might improve tracking of low-molecular-weight soluble photosynthates.

**Conclusion.** By combining pulse-chase double stable-isotopic labeling (13C and 15N) with TEM ultrastructural and NanoSIMS isotopic imaging, we have visualized and quantified at subcellular levels the incorporation and turnover of C and N in the symbiotic reef-building coral *P. damicornis*. These results provide a qualitative baseline of subcellular allocation and turnover of C- and N-containing photosynthates in the coral-dinoflagellate symbiosis. In the future, more precise quantitative C and N budgets for symbiotic reef corals could be constructed, using additional respiration and photosynthesis measurements. Moreover, alterations in the pattern of C and N utilization by symbiotic corals might be more precisely characterized in response to heterotrophic feeding and to global environmental changes.

**MATERIALS AND METHODS**

**Design of 13C and 15N dual isotopic labeling experiments.** Experiments were carried out on microcolonies (~5 cm tall) of the reef-building coral *Pocillopora damicornis* (Linnaeus, 1758) prepared from one large colony grown at the Aquarium Tropical, Palais de la Porte Dorée, Paris, France. Coral microcolonies were acclimated for 4 weeks prior to experimental manipulation in a large tank equilibrated with fish and benthic organisms, filled with artificial seawater (Instant Ocean Salts) and containing low nutrient concentrations (NH4+, <1 μM; NO3−, <1 μM; NO2−, <5 μM; PO43−, <1 μM [Salifert tests]). The temperature was 25 ± 1°C, the salinity was 35 ± 1‰, and the pH was 8.1 ± 0.1. Light irradiance of 100 μmol · m−2 · s−1 in the photosynthetically active radiation range was provided by 8 fluorescent T5 tubes of 39 W (6 × 10,000 K, 2 × 20,000 K) with 12-h/12-h light/dark cycling. During the acclimatization period of 4 weeks and subsequent experiments, coral microcolonies were not fed with plankton and therefore mostly relied on the uptake and assimilation of particulate and dissolved organic matter and on the autotrophic input from their photosynthetic dinoflagellate symbionts.

Isotopic dual labeling pulse-chase experiments were conducted in closed-system 20-liter glass tanks. In a first step, 17 coral microcolonies were incubated for 6 h in light in 0.2-μm-pore-filtered artificial seawater (adapted from Harrison et al. [50]), initially free of bicarbonate and nitrate, and supplemented with 2 mM [15N]bicarbonate (NaH15CO3, 99 atom% [Sigma-Aldrich]) and 30 μM [13C]nitrate (K13NO3, 98 atom% [Sigma-Aldrich]). This pulse of isotopic dual labeling started about 2 h after the onset of the light period. Then 5 coral microcolonies were transferred for a 186-h (8-day) chase period with light/dark cycling (12 h/12 h) in a tank filled with 20 liters artificial seawater sampled from the large acclimatization tank with normal C and N isotopic composition. The effect of coral autotrophic starvation on C and N remobilization pattern was investigated in a parallel 186-h chase experiment with 5 coral microcolonies exposed to similar conditions but maintained under constant darkness. During the chase phase, 25% of the incubation volume was renewed daily with artificial seawater from the large acclimatization tank. For TEM ultrastructural and NanoSIMS isotopic imaging, apices of coral branches were sampled with cutting pliers during the pulse-chase experiments at 0, 0.25, 0.5, 1, 3, 6, 12, 24, 48, 96, and 192 h, respectively. At each time step, a different coral microcolony (nubbin) was sampled, except at 6 h, where 3 replicate nubbins were sampled. Throughout the pulse-chase experiment under light/dark cycling, coral microcolonies displayed no...
macromorphological indications of stress (i.e., no unusual tentacle retraction, extensive mucus secretion, or paling). During the chase period, ammonium and nitrate concentrations fluctuated mildly between values of 1 to 4 μM and 5 to 10 μM, respectively, corresponding to closed-system aquarium conditions.

Contribution of nonphotosynthetic carboxylation reactions ("heterotrophic" C fixation) to [13C]bicarbonate incorporation by the symbiotic system and the effect of dark inhibition on [15N]nitrate assimilation by symbiotic dinoflagellates were assessed as follows: 3 coral microcolonies were pretreated for 24 h under constant darkness and then incubated for 6 h in darkness in a tank filled with 2 liters of 0.2-μm-pore-filtered artificial seawater (adapted from Harrison et al. [30]), initially free of bicarbonate and nitrate and supplemented with 2 mM [13C]bicarbonate (NaH13CO3, 99 atom% [Sigma-Aldrich]) and 30 μM [15N]nitrate (K15NO3, 98 atom% [Sigma-Aldrich]). Such extended pretreatment under darkness is required to effectively inhibit DIN assimilation in symbiotic reef corals (5, 33). Apexes of coral branches were sampled with cutting pliers at 0, 3, and 6 h during the labeling pulse.

To limit spatial fluctuations due to metabolic heterogeneities along coral branches or between different coral tissue areas (51–53), TEM ultrastructural observations were systematically performed on coral tissue sampled from the subapical area of light-exposed branches, within the coenosarcal connective tissue surrounding polyp units together (see Fig. S1 in the supplemental material).

TEM ultrastuctural observations. Coral samples were chemically fixed for 24 h at room temperature in Sörensen-sucrose phosphate buffer (0.1 M phosphate at pH 7.5, 0.6 M sucrose, 1 mM CaCl2) containing both 2.5% glutaraldehyde and 1% formaldehyde. They were then decalified for 4 to 5 days in 0.1 M Sörensen phosphate buffer containing 0.5 M EDTA at 4°C. Tissue samples were dissected under the stereomicroscope into small pieces containing one or two polyps, postfixed 1 h at room temperature with 1% OsO4 in 0.1 M Sörensen phosphate buffer, dehydrated in graded series of ethanol (50, 70, 90, and 100%), and embedded in Spurr’s resin. Tissue was preferentially oriented to obtain longitudinal sections parallel to the vertical growth direction of polyps. Sections were cut with a Diatome 45° diamond knife. Semithin sections (~0.5 μm) were stained with methylene blue-Azur II and observed with a Zeiss Axio Imager Z2 light microscope equipped with a Zeiss AxiocamMrc 5 digital camera. Ultrathin sections (~70 to 90 nm) were mounted on Formvar carbon-coated alphanumerics contrasted with 4% uranyl acetate and Reynold’s lead citrate solution. Ultrastuctural observations were carried out at 80 kV with a Philips CM 100 transmission electron microscope within the Electron Microscopy Facility (EMF) at the University of Lausanne (Switzerland).

Quantitative NanoSIMS isotopic imaging and ROI definition. In order to image and quantify in situ the subcellular distribution of 13C and 15N enrichment within endosymbiotic dinoflagellate cells and coral host tissue, the exact same areas in the coral tissue images were analyzed by NanoSIMS 50L ion microprobe in the Laboratory for Biological Geochemistry (EPFL, Lausanne, Switzerland), enabling direct correlation of ultrastructural (TEM) and isotopic (NanoSIMS) images.

TEM grids were mounted on 10-mm aluminum stubs with double-stick Cu tape and coated with a 10-nm thickness of gold. They were bombarded with a 16-keV primary ion beam of Ca+ (1 to 3 pA) focused to a spot size of about 100 to 150 nm on the sample surface. Secondary molecular ions [13C2]-, [12C13C]−, [12C15N]−, and [13C15N]− were simultaneously collected in electron multipliers at a mass resolution sufficient to avoid potentially problematic isobaric interferences on [13C2]− and [12C15N]−. Charge compensation was not necessary. Isotopic images ranging between 5 × 5 μm2 and 50 × 50 μm2 were obtained by rastering the primary beam across the sample surface with a dwell time of 5 ms. [13C13C] and [13C15N]/[15N] ratio distribution maps were obtained by taking the ratio between the drift-corrected [13C2]− and [12C15N]− signals and [13C13C]− and [12C15N]− images, respectively. [13C13C] and [13C15N] enrichments were expressed in the following delta notations:

\[ \delta^{13}C (\%) = \left( \frac{C_{mes}}{C_{nat}} - 1 \right) \times 1,000 \]  

\[ \delta^{15}N (\%) = \left( \frac{N_{mes}}{N_{nat}} - 1 \right) \times 1,000 \] 

where \( C_{mes} \) is the measured [13C]/[12C] ratio and \( C_{nat} \) is the average natural [13C]/[12C] ratio measured several times per day in nonlabeled, identically prepared coral samples throughout the period of NanoSIMS analyses and where \( N_{mes} \) is the measured [15N]/[14N] ratio and \( N_{nat} \) is the average natural [15N]/[14N] ratio measured several times per day in nonlabeled, identically prepared coral samples throughout the period of NanoSIMS analyses.

For each ultrathin section analyzed (for each coral microcolony sampled at each time step of the pulse-chase experiments), ~12 NanoSIMS isotopic maps were acquired to obtain a representative view of both isotopic enrichment and spatial distribution within the coral-dinoflagellate system. All analyzed dinoflagellates in this study were located in the oral gastroderm epithelium, which contains by far the highest density of symbiotic cells compared to the aboral gastroderm (see Fig. S1 in the supplemental material).

Data were processed using the-LIMAGE software. A smooth width of 3 pixels was applied for NanoSIMS 13C/12C and 15N/14N isotopic images, and a line width of 1 pixel was applied when illustrative line scans were defined from these smoothed images. NanoSIMS quantification of both 13C and 15N enrichments was carried out by defining regions of interest (ROIs), as illustrated in Fig. S2 in the supplemental material. For the whole dinoflagellates and their C reserves (i.e., starch granules and LDs), the ROIs were defined by drawing their contours. Quantification of the remaining cell compartments (i.e., the whole dinoflagellate cell minus the C reserves) was obtained by subtracting corresponding ROIs. In the coral host tissue, ROIs were defined as circles of 2 to 3 μm covering each of the four coral epithelia, avoiding the mesogela and intercellular spaces. For coral LDs, ROIs were obtained by drawing their contours. Because their small size (~50 nm in diameter) prevented accurate drawing of ROIs around each glycogen granule, their accumulation and turnover were assessed qualitatively from NanoSIMS line scans, and the spatial correlation between isotopic labeling and glycogen granules was confirmed in merged TEM and NanoSIMS images.

Importantly, conventional TEM sample preparation (i.e., chemical fixation with aldehydes and osmium tetroxide postfixation, followed by decalification and ethanol dehydration) extracts most low-molecular-weight soluble compounds and diffusible ions located in coral and dinoflagellate cells. Consequently, we imaged with NanoSIMS 13C and 15N incorporation into macromolecules (e.g., proteins, unsaturated lipids, and carbohydrates, such as glycogen and starch) stabilized by the sample preparation procedure.

Statistical analyses. Data were statistically analyzed with the R software. Shapiro-Wilk and Bartlett tests were used to assess data normality and homoscedasticity. In the case of non-Gaussian distributions, the non-parametric Kruskal-Wallis test was applied combined with a pairwise Wilcoxon rank sum test, instead of the one-way analysis of variance (ANOVA) combined with a pairwise t test. Holm’s correction was systematically employed when doing pairwise multiple-comparison tests. Results were considered significant at the 5% level.

SUPPLEMENTAL MATERIAL

Supplemental material for this article may be found at http://mbio.asm.org/lookup/suppl/doi:10.1128/mBio.02299-14/-/DCSupplemental.
ACKNOWLEDGMENTS

This work was supported by European Research Council advanced grant 246749 (BIOCARB), Fonds National Suisse grant CR2312-141048, and the École Polytéchnique Fédérale de Lausanne to A.M., CNRS grant Interface 2010 (NanoSIMS and symbiosis) to I.D.C., and the Faculty of Biology and Medicine of the University of Lausanne.

We thank Jean Daraspe, Chakib Djediat, Celine Loussett, and Antonio Micucciolo for providing help with TEM preparations. We are grateful for access to and expert help with aquarium facilities at ATPD, in particular to Jean-Daniel Galois and Sylvain Joumiere. Mathieu Peronne, Stephanie Cohen, and Thomas Krueger are thanked for discussions. Two anonymous reviewers are thanked for highly constructive comments and suggestions that helped improve the manuscript.
