(Dated: February 13, 2020)

We study the dynamics of entanglement in the scaling limit of the Ising spin chain in the presence of both a longitudinal and a transverse field. We present analytical results for the quench of the longitudinal field in critical transverse field which go beyond current lattice integrability techniques. We test these results against a numerical simulation on the corresponding lattice model finding extremely good agreement. We show that the presence of bound states in the spectrum of the field theory leads to oscillations in the entanglement entropy and suppresses its linear growth on the time scales accessible to numerical simulations. For small quenches we determine exactly these oscillatory contributions and demonstrate that their presence follows from symmetry arguments. For the quench of the transverse field at zero longitudinal field we prove that the Rényi entropies are exactly proportional to the logarithm of the exponential of a time-dependent function, whose leading large-time behaviour is linear, hence entanglement grows linearly. We conclude that, in the scaling limit, linear growth and oscillations in the entanglement entropies do not appear related to integrability and its breaking respectively.

Introduction.— Over the past two decades one-dimensional many body quantum systems have become ubiquitous laboratories to scrutinize fundamental aspects of statistical mechanics and condensed matter theory. On the one hand, out-of-equilibrium protocols featuring unitary dynamics, such as quantum quenches, have been commonly employed to test relaxation and thermalization hypothesis [1, 2]. On the other hand, almost perfect isolation from the environment and coherent evolution on time scales longer than milliseconds [3–6], are now a reality in trapped ultracold atoms [7]. This is an experimental breakthrough that promoted one-dimensional quantum models such as spin chains [8] to promising devices for quantum computation. It has been emphasized [9] how the presence of conservation laws and integrability are responsible for the appearance of Generalized Gibbs Ensembles [10], while their breaking can lead to prethermalization plateaux (see [11] and references therein). Transport phenomena in one dimension and their interplay with integrability have been also understood in an effective hydrodynamical setting [12, 13] which has been experimentally tested [14]. Nonetheless, given an initial state, it is still an open question whether and how local observables will equilibrate after a quench [15, 16].

In this respect, entanglement dynamics [17] furnishes a powerful diagnostic. In 1+1 dimensions, linear-in-time increase of the entanglement entropies has been associated with exponentially fast relaxation of local observables [18–20]. This characteristic growth has been further conjectured to be a generic feature of integrable models [21], where it has been analysed within a quasiparticle picture, inspired by conformal field theory [17] and free fermion calculations [22]. In such a framework, entangled quasi-particle pairs propagate freely in space-time and generate linearly growing entropies. Interactions are relevant when they break integrability and confine quasi-particles. Numerical studies in the Ising spin chain [23] and its scaling limit [24–27] indicated that, in presence of confinement, entanglement growth is strongly suppressed while local observables feature persistent oscillations whose frequencies coincide with the meson masses. Similar lack of relaxation has been found later in a variety of physical models spanning from gauge theories [28–31] and fractons [32] to Heisenberg magnets [33] and systems with long-range interactions [34]. Minimal models, with random unitary dynamics, that permit explicit entanglement calculations have been also proposed recently [35, 36] again in connection with quantum chaos [37–39] and non-integrable systems. However, apart from these and other [40, 41], in part phenomenological, predictions few exact results for the out-of-equilibrium entanglement of interacting models exist.

In this Letter, we put forward a unified picture to address perturbatively questions about entanglement dynamics and relaxation in gapped 1+1 dimensional systems close to a Quantum Critical Point (QCP). The formalism combines the perturbative approach of [42, 43] with the mapping in the scaling limit between powers of the reduced density matrix and correlation functions of a local field, called the branch point twist field [44, 45].
For massive systems, this mapping has been successfully employed at equilibrium [46] and recently also in a time-dependent context [47]. Crucially, its conclusions do not rely on any a priori assumption about the space-time evolution of the quasi-particles.

Focussing on the illustrative example of a quench of the longitudinal field in the Ising spin chain, we will provide examples of how bound state formation and symmetries of the twist field are responsible for slow relaxation of local observables and oscillations in the entanglement entropies. Although derived through field theory techniques our results are tested numerically in the lattice model in the scaling limit and very good agreement is found.

Model.— Consider the Ising spin chain defined by the Hamiltonian

$$H_{\text{lattice}} = - \sum_{n \in \mathbb{Z}} \left[ \sigma_n^x \sigma_{n+1}^x + h_z \sigma_n^z + h_x \sigma_n^x \right].$$

The Ising chain is a prototype of a quantum phase transition with spontaneous breaking of $\mathbb{Z}_2$ symmetry (acting as: $\sigma_n^x \to -\sigma_n^x$) and is critical for $h_z = 1$ and $h_x = 0$. At criticality, low energy excitations are massless free Majorana fermions described by a conformal field theory with central charge $c = 1/2$ [48]. Within the renormalization group framework, near the QCP, expectation values of local operators in the spin chain can be calculated from the Quantum Field Theory (QFT) action

$$A_0 = A_{\text{CFT}} - \lambda_1 \int dx \, dt \, \varepsilon(x,t) - \lambda_2 \int dx \, dt \, \sigma(x,t),$$

which is the celebrated Ising field theory (IFT) [49–51]. In Eq. (2), the conformal invariant action $A_{\text{CFT}}$ is perturbed by the $\mathbb{Z}_2$ even field $\varepsilon$ (energy), which is the continuum version of the lattice operator $\sigma_n^x$, and the $\mathbb{Z}_2$ odd field $\sigma$ (spin), which is instead the continuum version of the order parameter $\sigma_n^x$. The coupling constant $\lambda_1$ is proportional to the deviation of the transverse field from its critical value $h_z = 1$, while $\lambda_2$ is proportional to the longitudinal field $h_x$. At the QCP, the scaling dimension of $\sigma$ is $\Delta_\sigma = 1/8$ and that of $\varepsilon$ is $\Delta_\varepsilon = 1$.

Let $|\Omega\rangle$ be the ground state of the Hamiltonian $H$ of the field theory (2). Following a widely studied non-equilibrium protocol, dubbed quantum quench, at time $t = 0$ one of the two coupling constants $\lambda_i$ ($i = 1,2$) is modified according to $\lambda_i \to \lambda_i + \delta\lambda$. The evolution of the pre-quench ground state $|\Omega\rangle$ is governed by the perturbed Hamiltonian

$$G(t) := H + \theta(t) \delta\lambda \int dx \, \Psi(x),$$

$\Psi$ being either the spin or the energy field and $\theta(t)$, the Heaviside step function. This dynamical problem is analytically not solvable in general [42]. To provide theoretical predictions for local observables and entanglement entropies following a quench, one thus sets up a perturbative expansion in the relative quench coupling $\frac{\delta\lambda}{H} \ll 1$.

Perturbation Theory.— We revisit and extend to include entanglement calculations, the perturbative approach to the quench problem [42]. In scattering theory, it is possible to consider a basis of in and out states, denoted by $|\alpha\rangle_{\text{in}}|\alpha\rangle_{\text{out}}$, which are multi-particle eigenstates of the Hamiltonian $H = G(-\infty)$. The single particle momenta $p_i \in \mathbb{R}$ are ordered in a decreasing or increasing sequence, respectively. Similar eigenstates are constructed for the post-quench Hamiltonian $H_{\text{post}} := H + \delta\lambda \int dx \, \Psi(x) = G(\infty)$. The initial state $|\Omega\rangle$ can be formally expanded into the basis of the out-states of $H_{\text{post}}$ as: $|\Omega\rangle = \sum |\alpha\rangle_{\text{out}}$. Assuming for simplicity a unique family of particles, $|\alpha\rangle_{\text{out}}$ is then the multiparticle out-state $|p_1,\ldots,p_n\rangle_{\text{out}}$ while the symbol $\sum_{\alpha}$ is a shorthand notation for $\sum_{p_1<\ldots<p_n} \int \frac{dp_j}{2\pi}$. Let $\tilde{e}(p) := \sqrt{m^2 + p^2}$ and $m$ the mass of a particle in the post-quench theory. The overlap coefficients $c_\alpha$ are the elements of the scattering matrix for the quench problem in Eq. (3). Passing to the interaction picture with respect to $H$, one has [52]

$$|\Omega\rangle = |\Omega\rangle_{\text{post}} + 2\pi\delta\lambda \sum_{\alpha \neq \Omega} \frac{\delta(P^{\alpha})}{E^{\alpha}} \langle F^{\Psi^{\alpha}} | \alpha\rangle_{\text{out}} |\Omega\rangle_{\text{post}} + O(\delta^2).$$

(4)

In Eq. (4), $E^{\alpha}$ and $P^{\alpha}$ are the pre-quench energy and momentum of the state $|\alpha\rangle_{\text{out}}$; $\delta(x)$ is the Dirac delta and the function $I^{\alpha}$ is the form factor: $I^{\alpha} := \langle \Omega | \Psi(0,0) | \alpha\rangle_{\text{in}}$, calculated in the pre-quench theory. The second order correction to Eq. (4) has been also considered recently [53]. From the expansion in Eq. (4), it follows

$$\langle \Omega | e^{iH_{\text{post}} t} \Phi(0,0) e^{-iH_{\text{post}} t} | \Omega\rangle = \langle \Omega | \Omega \rangle_{\text{post}} + 4\pi\delta\lambda \sum_{\alpha \neq \Omega} \frac{\delta(P^{\alpha})}{E^{\alpha}} \text{Re} \left( e^{-itE^{\alpha}} \langle F^{\Psi^{\alpha}} | \alpha\rangle_{\text{out}} |\Omega\rangle_{\text{post}} \right) + O(\delta^2),$$

(5)

with now $E^{\alpha}$ the energy of the state $|\alpha\rangle_{\text{out}}$. At $O(\delta\lambda)$, one can replace $|\alpha\rangle_{\text{out}}$ by $|\alpha\rangle_{\text{out}}$ inside the sum in Eq. (5) and use known properties of the form factors to relax the ordering prescription on the momenta of the outstates [54]. We will further denote by $\sum \int \frac{dp_j}{2\pi} \int \frac{dp_j}{2\pi}$ with $e(p) := \sqrt{m^2 + p^2}$ and $m_0$ the particle mass in the pre-quench theory. Since $m - m_0 = O(\delta\lambda)$, the first order correction to the expectation value of a local operator after the quench is [42, 43]

$$\langle \Omega | e^{iH_{\text{post}} t} \Phi(0,0) e^{-iH_{\text{post}} t} | \Omega\rangle = \langle \Omega | \Omega \rangle_{\text{post}} + 4\pi\delta\lambda \sum_{\alpha \neq \Omega} \frac{\delta(P^{\alpha})}{E^{\alpha}} \text{Re} \left( e^{-itE^{\alpha}} \langle F^{\Psi^{\alpha}} | \alpha\rangle_{\text{out}} F^{\alpha} \right) + O(\delta^2).$$

(6)
Consider now a semi-infinite spatial bipartition of the Hilbert space of the QFT associated to the quench problem (3). In particular, let $\mathcal{L}$ be the semi-infinite negative real line and $\mathcal{R}$ the semi-infinite positive real line and denote by $\rho_R(t) := \text{Tr}_{\mathcal{L}}[e^{-itH_{\text{post}}}|\Omega]\langle\Omega|e^{itH_{\text{post}}}]$, the reduced density matrix after the quench obtained tracing over the left degrees of freedom. In QFT, half-space Rényi entropies after a quench $S_n(t) := \frac{1}{1-n}\log[\text{Tr}_R\rho_R](t)$ are related to the one-point function of the twist field $T_n$ [44, 45] by

$$S_n(t) = \frac{1}{1-n}\log \left[ \epsilon^{\Delta_{T_n}} \langle \Omega | T_n(0,t) | \Omega \rangle \right]. \tag{7}$$

In Eq. (7), $\epsilon$ is a short distance cut-off and $\Delta_{T_n} = \frac{c}{12}(n^{-1} - n^{-2})$ is the scaling dimension of the twist field at the QCP [55–57]. The von Neumann entropy $S(t)$ is defined through the limit $S(t) := \lim_{n \to 1} S_n(t)$.

In writing Eq. (7), a new difficulty arises: the expectation value of the twist field has to be calculated in an $n$-fold replicated QFT and the time evolution of the twist field after the quench is governed by the replicated Hamiltonian $\sum_{r=1}^n \hat{H}^{(r)} + \delta_{\lambda} \int dx \Psi^{(r)}$, $r$ being the replica index. However, when calculating the overlaps $\langle \alpha|\Omega \rangle$ at first order in $\delta_{\lambda}$, the sum over the replica trivializes since the perturbing field $\Psi^{(r)}$ has non-vanishing matrix elements only between particles in the same copy. One therefore gets Eq. (4) with a prefactor $n$ in front of the sum, which only involves states within one particular replica, for instance the first. The first order expansion of the twist field one-point function after a quench is then

$$\langle \Omega | T_n(0,t) | \Omega \rangle = \langle \Omega | T_n(0,0) | \Omega \rangle_{\text{post}} + 4\pi n \delta_{\lambda} \sum_{\alpha \in \text{rep}} \frac{\delta_0^{(P_{\alpha})}}{E^2_{\alpha}} \text{Re} \left[ e^{-itE_{\text{post}}(P_{\alpha})} F_{\alpha} T_n \right] + O(\delta_{\lambda}^2), \tag{8}$$

where, as indicated, the sum only contains states in the first replica. Similarly to the discussion around Eq. (6), $F_{\alpha} T_n$ in Eq. (7) denotes the pre-quench twist-field matrix element $F_{\alpha} T_n = \langle \Omega | T_n(0,0) | \alpha \rangle$.

**Longitudinal Field Quench.**—We examine a quench along the vertical axis of the phase diagram of the IFT depicted in Fig. 1. This quench, cf. Eq. (2), involves a sudden change of the coupling $\lambda_2$ at its critical value, i.e. $\lambda_1 = 0$. In the lattice model described by Eq. (1), it modifies the longitudinal field $h_x \to h_x + \delta_{h_x}$ at fixed transverse field $h_z = 1$. In the presence of a longitudinal field, the Ising spin chain is strongly interacting and the perturbative approach is the only analytical device to study entanglement dynamics.

From a QFT perspective, at $\lambda_1 = 0$ and $\lambda_2 \neq 0$, both the pre- and post-quench theories are integrable. The spectrum contains of eight stable particles [49, 58], whose masses are in correspondence with the components of the Perron-Frobenius eigenvector of the Cartan matrix of the Lie algebra $E_8$. We will refer to such a field theory, in short, as the $E_8$ field theory, see Fig. 1. The masses of the eight particles have been partially measured experimentally [59] and numerically estimated in the scaling limit using matrix product states [60]. In the $E_8$ field theory both the spin operator and the twist field couple to the eight one-particle states. Eqs. (6) and (8), predict in this case that at $O(\delta_{\lambda})$ the one-point function of the spin and the entanglement entropies must oscillate in time without relaxing. The first-order result for the order parameter [43] is re-obtained in [61]. For the time evolution of the entanglement entropies, perturbation theory, combined with Eq. (7), gives at large times

$$S_n(t) - S_n(0) \approx \frac{\delta_{\lambda}}{\lambda_2} \left[ \frac{2n C_\sigma}{1-n} \sum_{a=1}^8 \frac{F_{\alpha} T_n}{r_a} \cos(m r_a) t \right] + O(\delta_{\lambda}^2). \tag{9}$$

where the coefficient $C_\sigma = -0.065841 \ldots$ and the (real) normalized pre-quench one-particle form factors of the spin field [63], $F_{\alpha}$, and the twist field [64], $F_{\alpha} T_n$ are also summarized in [61]. The universal ratios $r_a$ in Eq. (9) are the masses of the particles in the $E_8$ field theory normalized by the mass of the lightest particle, whose value after the quench is $m$. It is finally possible to extrapolate the results for the Rényi entropies to $n \to 1$, and predict the long-time limit of the von Neumann entropy. There are subleading corrections in time to Eq. (9) of order $t^{-3/2}$ (but of leading order in $\delta_{\lambda}$) which are discussed in [61].

The field theoretical result in Eq. (9) can be tested against numerical simulations through matrix product states in the Ising spin chain near the QCP. For finding the initial state and for the time evolution we use the iTEBD algorithm [65, 66] extrapolated to the scal-
\( \delta h_x / h_x = 0.04 \quad \delta h_x / h_x = 0.05 \)

\[ \Delta S_1 \times 10^3 \]

\[ 10^{-1} \quad 10^{-2} \quad 10^{-3} \quad 10^{-4} \]

\[ m_2 \quad m_3 \quad m_4 \]

FIG. 3. Numerical Fourier transform of the variation of the von Neumann entropy (related to the variable \( mt \)) for quenches with \( \delta h_x / h_x = 0.05 \) (solid) and \( \delta h_x / h_x = -0.04 \) (dashed). Vertical lines indicate different frequencies. The horizontal lines mark the peaks corresponding to the masses of the four lightest particles. From top to bottom they correspond to \( m_1, m_2, m_3 \) and \( m_4 \), respectively. The dashed horizontal line is set by hand, and the three dotted horizontal lines were calculated from the ratios of the one-particle form factors based on Eq. (9).

ing limit, details are given in [61]. In a non-equilibrium protocol, the longitudinal field is quenched from \( h_x \) to \( h_x + \delta h_x \) with \( \delta h_x / h_x = \delta \lambda / \lambda_2 = -0.04, 0.05 \). Due to the absence of visible linear growth of the entanglement entropies [61], the simulation can reach large enough time to carry out a Fourier analysis. The non-universal mass coupling relation is obtained by fitting the numerical data for the order parameter to the theoretical curve given in [61], and we have \( m \approx 5.42553(h_x + \delta h_x)^{8/15} \), consistent with earlier estimates [60, 67].

According to Eq. (9), in the scaling limit, with time measured in units of \( m^{-1} \), the time evolution of the entanglement entropies should follow a universal curve. The numerical results for real time evolution in the scaling region are summarized in Fig. 2 for the von Neumann and the second Rényi entropy, showing excellent agreement with theoretical predictions obtained from Eq. (9). The curves for the entanglement entropies have been shifted vertically to take into account second order corrections [47] to the twist field post-quench vacuum expectation value \( \langle \Omega| T_n(0,0) |\Omega\rangle_{\text{post}} \), cf. Eq. (8) and [61]. In Fig. 3 we also show the numerical Fourier spectrum of the von Neumann entropy calculated from extrapolated data up to \( mt = 170 \). The Fourier transform was carried out with respect to the rescaled time \( mt \), therefore the main frequency is at \( \tilde{\omega} = 1 \) for both quenches. The various peaks are related to the mass ratios of different particles summarized in [61]. For infinite time the one

particle peaks would be \( \delta \)-function peaks, but for finite time they have finite height. The height ratios are related to form factors of the longitudinal field and the twist fields through Eq. (9). The horizontal line in Fig. 3 related to the lightest particle is set by hand, the ones related to \( m_2, m_3 \) and \( m_4 \) are calculated from the form factors given in [61].

Transverse Field Quench. — We consider now a quench of the transverse field \( h_z \rightarrow h_z + \delta h_z \) for longitudinal field \( h_x = 0 \). In the IFT, see Fig. 1, this protocol displaces along the horizontal axis of the phase diagram: \( \lambda_1 \rightarrow \lambda_1 + \delta \lambda \), modifying the mass of the Majorana fermion [19, 68]. The ground state \( |\Omega\rangle \) of the pre-quench theory can be expanded in the post-quench quasi-particle basis as

\[ |\Omega\rangle = \exp \left[ \int_0^\infty \frac{dp}{2\pi \varepsilon(p)} \tilde{K}(p) a_{\text{post}}^\dagger (-p) a_{\text{post}}^\dagger (p) \right] |\Omega\rangle_{\text{post}} , \]

(10)

where the function \( \tilde{K}(p) \) is given in [68] and \( a_{\text{post}}^\dagger (p) \) are post-quench fermionic creation operators. Due to the properties of the free fermionic form factors, the expectation value of the twist field exponentiates

\[ \frac{\langle \Omega| T_n(0,t) |\Omega\rangle_{\text{post}}}{\langle \Omega| T_n(0,0) |\Omega\rangle_{\text{post}}} = \exp \sum_{k,l=0}^{\infty} D_{2k,2l}^c(t) . \]

(11)

For a proof of Eq. (11), we refer to the Supplementary Material [61]. The amplitudes \( D_{2k,2l}^c(t) \) contribute at
leading order \((\delta \lambda / \lambda)^{k+l}\) in perturbation theory and can be systematically computed. Differently from Eq. (9), the oscillatory first order term is \(O(t^{-3/2})\) for large time, while in [47] it was shown that \(D_{2,2}^c(t) = \left(\delta \lambda / \lambda\right)^2 [-|A|t + O(1)]\). In the absence of interactions, exponentiation of second order contributions, leads then to linear growth of the Rényi entropies as a by-product of relaxation of the twist-field one-point function.

**Discussion.** — Absence of relaxation of the order parameter and persistent oscillations in the entanglement entropies have been observed previously in several numerical investigations of the Ising spin chain and its scaling limit [23–27]. In those works, confinement of the pre-quench excitations, due to a longitudinal field, has been advocated as a possible explanation of the phenomenon. Near a QCP, perturbation theory [42, 43] qualitatively, and quantitative at first order, captures the origin of these oscillatory behaviours. For the entanglement entropies, oscillations are a consequence of the twist field having non-vanishing matrix elements between the initial state and single-particle eigenstates of the post-quench Hamiltonian. This is expected in any massive interacting QFT without fine-tuning of the initial state [53] and independently from integrability. A similar mechanism has been invoked to explain absence of relaxation in the one-point function of local observables in different contexts [34, 69, 70]. The fate of oscillations at higher orders in perturbation theory will determine whether or not entanglement grows and set the time-scale for local relaxation [9]. In certain interacting QFTs [71] it has been argued that resummation of the perturbation theory could lead to superexponential damping of the oscillatory first order result [72]. The issue is however still unsettled, due to formidable technical complications. Nevertheless, we performed additional numerical calculations presented in [61], which indicate that along the \(E_8\) line, the order parameter does not relax (i.e. oscillates) and entanglement growth is strongly suppressed also for large quenches. This suggests that our analysis of the longitudinal field quench in the Ising spin chain remains qualitatively correct also for relative quench couplings of order one. It is a relevant and open question to identify on the lattice model a mechanism, preventing entanglement growth; it is possible that exotic conservation laws [33, 73] may play a role. We finally observe that the formalism discussed here could be adapted to local quenches, following [74].

**Acknowledgements.** — We are grateful to A. Cubero, A. Delfino and G. Takács for numerous comments on the first version of this paper. OACA and IMSZ gratefully acknowledge support from EPSRC through the standard proposal “Entanglement Measures, Twist Fields, and Partition Functions in Quantum Field Theory” under reference number EP/P006108/1. They are also grateful to the International Institute of Physics in Natal (Brazil) for support during the workshop “Emergent Hydrodynamics in Low-Dimensional Quantum Systems” held in May 2019 during which discussions relating to this work took place. The work of IMSZ was supported by the grant “Exact Results in Gauge and String Theories” from the Knut and Alice Wallenberg foundation; JV is supported by the Brazilian Ministries MEC and MCTC and the Italian Ministery MIUR under the grant PRIN 2017 “Low-dimensional quantum systems: theory, experiments and simulations”. Part of ML’s work was carried out in the International Institute of Physics in Natal (Brazil), where his research was supported by the Brazilian Ministeries MEC and MCTC. ML also acknowledges support provided from the National Research, Development and Innovation Fund of Hungary, financed under the PD 132118 funding scheme. We thank the High-Performance Computing Center (NPAD) at UFRN for providing computational resources.

The Supplementary Material is organized as follows. In Section 1 we summarize the main analytical results that we have used in our Letter, particularly when comparing the predictions of quench perturbation theory \[1, 2\] to lattice numerical calculations in the scaling limit. These analytical results are principally the form factors of local fields in the theories under consideration. The fields involved here are the branch point twist field whose correlators are directly linked to measures of entanglement, and the field associated with the coupling whose sudden change generates the quench.

In our Letter we have mainly discussed the longitudinal field quench (for critical transverse field). In the QFT setting, this is equivalent to a mass quench in the \( E_8 \) minimal Toda field theory. The mass \( m_{0,1} \) of the lightest particle in the model before the quench (see Section 1) and the coupling constant \( \lambda_2 \) are related as

\[
m_{0,1} = \kappa \lambda_2^{\frac{8}{15}}, \quad \text{with} \quad \kappa = 4.40490858..., \quad (1)
\]

where the constant \( \kappa \) has an analytical expression in terms of \( \Gamma \)-functions first found in \[3\]. Therefore a change of the longitudinal field \( h_x \) proportional to \( \lambda_2 \) is equivalent to a change of the masses of the eight particles in the spectrum, which are all multiples of \( m_{0,1} \). As shown in Fig. 1 and equation (2) of the Letter, in the QFT, the perturbing field is the spin field \( \sigma(x,t) \). We analyze such a quench in Section 1 of the supplementary material.

In Section 2, we also present a complete proof of the exponentiation of the one-point function of the branch point twist field in the case of a transverse field quench (for zero longitudinal field). That is equivalent to a mass quench in Ising field theory since now the fermion mass \( m_0 \) is proportional to \( |h_z - 1| \), where \( h_z \) is the transverse field. Our proof complements the detailed study presented in \[4\]. In this case the perturbing field is the energy field \( \varepsilon(x,t) \) as also shown in Fig. 1 of the Letter.

In Section 3 we provide a description of the numerical techniques, with additional results not included in the Letter. Finally in Section 4 we comment on the robustness of entanglement oscillations at higher order in perturbation theory.

1 Longitudinal Field Quench: Mass Quench in \( E_8 \) Minimal Toda Field Theory

Let us start by fixing the basic definitions and notations for the form factors that we have employed in the present work. Although in our Letter we have written formulae involving form factors of an arbitrary state \( |\alpha\rangle^{\text{out/in}} \), in practice the only form factors that have been analytically evaluated are those associated with one- and two-particle states. We will therefore only review those here. In a 1+1-dimensional QFT we define the one- and the two-particle form factors of a local, spinless field \( \mathcal{O} \) as the matrix elements

\[
F_{a_1}^\mathcal{O} := \langle \Omega | \mathcal{O}(0,0) | \theta_1 \rangle_{a_1}
\quad \text{and} \quad
F_{a_1 a_2}^\mathcal{O} (\theta_1 - \theta_2) := \langle \Omega | \mathcal{O}(0,0) | \theta_1 \theta_2 \rangle_{a_1 a_2}, \quad (2)
\]

where \( a_1, a_2 \) are particle quantum numbers, \( \theta_1, \theta_2 \) are rapidities, in terms of which—and with a slight abuse of notations—the energy and momentum are given by \( e_a(\theta) = m_{0,a} \cosh \theta \) and \( p_a(\theta) = m_{0,a} \sinh \theta \), where \( m_{0,a} \) is the mass of a particle of type \( a \) in the pre-quench theory. The state \( |\Omega\rangle \) is the pre-quench vacuum.
In general, $|\theta_1 \ldots \theta_k\rangle_{a_1 \ldots a_k}$, is an asymptotic in-state of $k$ particles and $|\Omega\rangle$ is the ground state. For spinless fields in relativistic QFT the one-particle form factors are rapidity-independent whereas the two-particle form factors depend only upon rapidity differences, hence our notation. It is also useful to introduce the normalized one-particle form factor as

$$\hat{F}_a(\theta) := \frac{\langle \Omega | \mathcal{O}(0,0) | \theta \rangle_{a_1}}{\langle \Omega | \mathcal{O}(0,0) | \Omega \rangle} = \hat{\sigma},$$

for the spin field and the twist field we will use the shorthand notation $\langle \Omega | \sigma(0,0) | \Omega \rangle = \sigma$ and $\langle \Omega | T_n(0,0) | \Omega \rangle = \tau_n$.

The $E_8$ minimal Toda field theory is an integrable model with diagonal scattering matrix and an eight particle spectrum. They were both first given in the seminal papers [5, 6]. The mass spectrum takes the form

$$r_2 = 2 \cos \frac{\pi}{5}, \quad r_3 = 2 \cos \frac{\pi}{3}, \quad r_4 = 2r_2 \cos \frac{7\pi}{30}, \quad r_5 = 2r_2 \cos \frac{2\pi}{15},$$

$$r_6 = r_2 r_3, \quad r_7 = r_2 r_4, \quad r_8 = r_2 r_5,$$

where $r_i := m_{0,i}/m_{0,1}$ (hence, $r_1 = 1$). It should be noticed that the ratios $r_i$ are the same for both the pre-quench and post-quench theories as a consequence of universality of the scaling limit.

### 1.1 One-Particle Form Factors

As we have seen in equation (10) of the Letter the calculation of the entanglement entropies is based upon the knowledge of the one-particle form factors of the branch point twist field and the spin field. So far the only computation of the twist field form factors in this theory was performed in [7]. There, explicit values of the form factors of the first four lightest particles for $n = 2$ were given, whereas for $2 < n \leq 4$ the values of $\hat{F}_n^T$ were presented graphically. However, while carrying out detailed comparison with the lattice results in the scaling limit, we realized that it was critical to have a more accurate evaluation of the quantities $\hat{F}_n^T$ with $n = 2, 3, 4$. The values given in [7] were dependent on the asymptotic behaviour of certain two-particle form factors, and we have realized that this asymptotic value was systematically underestimated in [7]. In Table 1 we present the values of $\hat{F}_n^T$ with $n = 2, 3, 4$ as newly obtained using a different technique (we will present further details in subsection 1.2). For $n = 2$ they differ from those presented in [7] by between 10% and 20% (depending on the particle). This has allowed us to reach a much improved matching with numerical values.

| $n$ | 2 | 3 | 4 |
|-----|---|---|---|
| $\hat{F}_{2}^{T}$ | -0.17124900374494678 | -0.1996259878353373 | -0.20930848250173 |
| $\hat{F}_{3}^{T}$ | 0.07005900535572894 | 0.08788104227633028 | 0.094313951168679 |
| $\hat{F}_{4}^{T}$ | -0.03440203483936546 | -0.04473113820315836 | -0.048562882373633 |
| $\hat{F}_{5}^{T}$ | 0.023657419056577746 | 0.031870010789866426 | 0.0349996171170825 |

Table 1: Newly evaluated (normalized) one-particle form factors of the branch point twist field for the four lightest particles in the spectrum. The hat in $\hat{F}_{n}^{T}$ indicates normalization by the vacuum expectation value of the branch point twist field.
As we can see, equation (10) in the Letter also requires the knowledge of one-particle form factors of the spin field. These were computed in [8, 9]. Their (normalized) values are given in Table 2.

| $\hat{F}_1^\sigma$ | $\hat{F}_2^\sigma$ | $\hat{F}_3^\sigma$ | $\hat{F}_4^\sigma$ |
|---------------------|---------------------|---------------------|---------------------|
| -0.64090211         | 0.33867436          | -0.18662854         | 0.14277176          |

| $\hat{F}_5^\sigma$ | $\hat{F}_6^\sigma$ | $\hat{F}_7^\sigma$ | $\hat{F}_8^\sigma$ |
|---------------------|---------------------|---------------------|---------------------|
| 0.06032607          | -0.04338937         | 0.01642569          | -0.00303607         |

Table 2: Normalized one-particle form factors of the spin field with $\hat{F}_i^\sigma = F_i^\sigma / \bar{\sigma}$, where $\bar{\sigma}$ is the expectation value of the spin field.

In order to compute the von Neumann entropy we also need the values of

$$g_a := \lim_{n \to 1} \frac{\hat{F}_a^T_n}{1 - n},$$  \hspace{1cm} (5)

It is well-known that the functions $\hat{F}_a^T_n$ tend to zero for $n \to 1$. However, the precise asymptotics was not investigated in [7]. This asymptotics can be studied by analysing the consistency equations that these form factors must satisfy and which were given in [7]. These give rise to a Taylor expansion in powers of $n - 1$, starting with power one. Once more, the derivation relies heavily on properties of the functions that enter the two particle form factors. We will briefly discuss these below. Table 3 gives the values of the first four functions $g_a$.

### 1.2 Two-Particle Form Factors

In [7] the two-particle form factors $F_{11}^T(\theta)$ and $F_{12}^T(\theta)$ were also computed. Here we are referring always to particles in the same copy so we omit copy numbers. They are given by

$$F_{11}^T(\theta) = \tau_n Q_{11}^T(\theta) \prod_{\alpha=\frac{1}{3}, \frac{2}{3}, \frac{4}{3}} B_{\alpha}(\theta; n) f_{11}(i\pi; n),$$  \hspace{1cm} (6)

and

$$F_{12}^T(\theta) = \tau_n Q_{12}^T(\theta) \prod_{\alpha=\frac{1}{3}, \frac{5}{3}, \frac{7}{3}, \frac{4}{3}} B_{\alpha}(\theta; n) f_{12}(i\pi; n),$$  \hspace{1cm} (7)

| $g_1$  | -0.4971505471133315 |
|-------|---------------------|
| $g_2$  | 0.10034674000675149 |
| $g_3$  | -0.0365919548726796 |
| $g_4$  | 0.01914945194919403 |

Table 3: The functions (5) for the four lightest particles in the spectrum.
with
\[ f_{11}(\theta; n) = -i \frac{\sinh \theta}{2n} \exp \left[ 2 \int_0^\infty \frac{dt}{t} \frac{\cosh \frac{t}{2} + \cosh \frac{\theta}{2} + \cosh \frac{3\theta}{2}}{\sinh \frac{3\theta}{2}} \sin^2 \left( \frac{i}{2} \left( n + i\theta \right) \right) \right], \] (8)
and
\[ f_{12}(\theta; n) = \exp \left[ 2 \int_0^\infty \frac{dt}{t} \frac{\cosh \frac{t}{2} + \cosh \frac{\theta}{2} + \cosh \frac{3\theta}{2}}{\sinh \frac{3\theta}{2}} \sin^2 \left( \frac{i}{2} \left( n + i\theta \right) \right) \right], \] (9)
where
\[ K_{11}(\theta; n) = \frac{\sinh \left( \frac{i\pi - \theta}{2n} \right) \sinh \left( \frac{i\pi + \theta}{2n} \right)}{\sin \frac{\pi}{n}}, \] (10)
\[ B_\alpha(\theta; n) = \sinh \left( \frac{i\pi \alpha - \theta}{2n} \right) \sinh \left( \frac{i\pi \alpha + \theta}{2n} \right), \] (11)
\( \tau_n \) is the vacuum expectation value of the branch point twist field and the functions \( Q_{11}^T(\theta) \) have the general structure
\[ Q_{11}^T(\theta) = A_{11}(n) + B_{11}(n) \cosh \frac{\theta}{n} + C_{11}(n) \cosh^2 \frac{\theta}{n}, \] (12)
and
\[ Q_{12}^T(\theta) = A_{12}(n) + B_{12}(n) \cosh \frac{\theta}{n} + C_{12}(n) \cosh^2 \frac{\theta}{n}, \] (13)
with coefficients that can be determined for each value of \( n \). They have also been re-evaluated with greater precision for this work and are listed in Table 4.

| \( n \) | 2 | 3 | 4 |
|---|---|---|---|
| \( A_{11}(n) \) | 0.05028656966443226 | 0.008222663493673649 | 0.003094920413703075 |
| \( B_{11}(n) \) | 0.0011995725313121055 | -0.005436476679120888 | -0.004685055209534106 |
| \( C_{11}(n) \) | 0.009415788449439522 | 0.0053536637424471565 | 0.0032612776790863058 |
| \( A_{12}(n) \) | -0.003893395394244009 | -0.0052884492808026595 | -0.0014212064608825764 |

| \( C_{12}(n) \) | -0.00484918093780377 | -0.00232762587055512 | -0.001176365122042212 |

Table 4: The coefficients of the functions \( Q_{11}^T(\theta) \) and \( Q_{12}^T(\theta) \).

At the heart of these improved values is the improved evaluation of the leading asymptotics of the functions \( f_{11}(\theta, n), f_{12}(\theta, n) \) for \( \theta \to \infty \). The understanding of this asymptotic plays an important role in fixing the one-particle form factors because the two-particle form factors are expected to satisfy the clustering property in momentum space, namely
\[ \lim_{\theta \to \infty} \frac{F_{a_1 a_2}^{T_n}(\theta)}{F_{a_1}^{T_n} F_{a_2}^{T_n}} = \frac{F_{a_1}^{T_n}}{F_{a_1}^{T_n} F_{a_2}^{T_n}}. \] (14)
For \( a_1 = a_2 = 1 \) and \( a_1 = 1, a_2 = 2 \) this gives two of the conditions that were employed in [7] to fix the one-particle form factors. It turns out that both functions \( f_{11}(\theta, n) \) and \( f_{12}(\theta, n) \) can be expressed as products of the following blocks:

\[
f(\theta, \alpha; n) = \exp \left\{ 2 \int_0^\infty \frac{dt \cosh \left[ t \left( \alpha - \frac{1}{2} \right) \right]}{\cosh \left( \frac{t}{2} \right)} \sinh^2 \left( \frac{t[i\pi n-\theta]}{2\pi} \right) \sinh (nt) \right\},
\]

for particular choices of \( \alpha \). In fact

\[
f_{11}(\theta, n) = f(\theta, 0; n) f(\theta, \frac{2}{3}; n) f(\theta, \frac{2}{5}; n) f(\theta, \frac{1}{15}; n),
\]

\[
f_{12}(\theta, n) = f(\theta, \frac{4}{5}; n) f(\theta, \frac{3}{5}; n) f(\theta, \frac{7}{15}; n) f(\theta, \frac{4}{15}; n).
\]

A natural simplification of the formula (15) that helps to extract the asymptotics is to pull out a factor \( f_0(\theta, n) := f(\theta, 0; n) \) using the integral representation

\[
f(\theta, \alpha; n) = f_0(\theta; n) \exp \left\{ 2 \int_0^\infty \frac{dt \cosh \left[ t \left( \alpha - \frac{1}{2} \right) \right]}{\cosh \left( \frac{t}{2} \right)} \sinh^2 \left( \frac{t[i\pi n-\theta]}{2\pi} \right) \sinh (nt) \right\}
\]

\[
= f_0(\theta; n) \exp \left\{ -4 \int_0^\infty \frac{dt \sinh \left( \frac{t}{2} \alpha \right) \sinh \left( \frac{t}{2}(1-\alpha) \right)}{\cosh \left( \frac{t}{2} \right)} \sinh^2 \left( \frac{t[i\pi n-\theta]}{2\pi} \right) \sinh (nt) \right\}
\]

\[
= f_0(\theta; n) N(\alpha; n) \exp \left\{ 2 \int_0^\infty \frac{dt \sinh \left( \frac{t}{2} \alpha \right) \sinh \left( \frac{t}{2}(1-\alpha) \right)}{\cosh \left( \frac{t}{2} \right)} \cos \left( \frac{t[i\pi n-\theta]}{\pi} \right) \sinh (nt) \right\},
\]

with

\[
N(\alpha; n) = \exp \left\{ -2 \int_0^\infty \frac{dt \sinh \left( \frac{t}{2} \alpha \right) \sinh \left( \frac{t}{2}(1-\alpha) \right)}{\cosh \left( \frac{t}{2} \right)} \sinh (nt) \right\}.
\]

For large \( \theta \), one can then show that

\[
\lim_{\theta \to \infty} f(\theta, \alpha; n) = N(\alpha; n) \lim_{\theta \to \infty} f_0(\theta; n) \sim \frac{N(\alpha; n)}{2t} e^{\frac{\theta}{\pi}}.
\]

It is easy to show that \( N(\alpha; n) \) are convergent integrals, but the remaining integral

\[
\tilde{I}(\theta, \alpha; n) = 2 \int_0^\infty \frac{dt \sinh \left( \frac{t}{2} \alpha \right) \sinh \left( \frac{t}{2}(1-\alpha) \right)}{\cosh \left( \frac{t}{2} \right)} \cos \left( \frac{t[i\pi n-\theta]}{\pi} \right) \sinh (nt)
\]

\[
= 4 \int_0^\infty \frac{dt \sinh \left( \frac{t}{2} \alpha \right) \sinh \left( \frac{t}{2}(1-\alpha) \right)}{\sinh (t)} \sinh \left( \frac{t}{2} \right) \cos \left( \frac{t[i\pi n-\theta]}{\pi} \right),
\]

needs regularization. Our strategy is to express the \( \sinh t \) in the denominator as

\[
\frac{1}{\sinh t} = 2 \sum_{k=0}^{N-1} e^{-(2k+1)t} + \frac{e^{-2Nt}}{\sinh t},
\]

\[
\text{(22)}
\]
and use the integral identity
\[
\int_0^\infty \frac{dt}{t} \frac{\sinh (\beta t) \sinh (\gamma t) e^{-\mu t}}{\sinh (\delta t)} = \frac{1}{2} \log \omega (\beta, \gamma, \mu, \delta)
\]
\[
= \frac{1}{2} \log \left( \frac{\Gamma \left( \frac{\beta + \gamma + \mu + \delta}{2} \right) \Gamma \left( \frac{-\beta + \gamma + \mu + \delta}{2} \right)}{\Gamma \left( \frac{-\beta + \gamma + \mu + \delta}{2} \right) \Gamma \left( \frac{-\beta + \gamma + \mu + \delta}{2} \right)} \right),
\]
(23)

The regularized integral then is
\[
\tilde{I} (\theta, \alpha, N; n) = 2 \int_0^\infty \frac{dt}{t} \frac{\sinh \left( \frac{1}{2} \alpha \right) \sinh \left( \frac{1}{2} (1 - \alpha) \right) \cos \left( \frac{k + n - \theta}{\pi} \right)}{\sinh (nt)} e^{-2Nt}
\]
\[
+ \sum_{k=0}^{N-1} \frac{1}{\omega \left( \frac{\alpha}{2}, \frac{1-\alpha}{2}, 2k + 1 \right) + n + i\frac{\theta}{\pi}, n)} \frac{1}{\omega \left( \frac{\alpha}{2}, \frac{1-\alpha}{2}, 2k + 1 \right) - n - i\frac{\theta}{\pi}, n)}.
\]
(24)

The asymptotics of the \( \Gamma \) function for large imaginary values is
\[
\lim_{y \to \infty} \Gamma (x + iy) \sim \sqrt{2\pi y^{x-1/2+iy} e^{-\pi y}} + O(1/y),
\]
(25)

hence
\[
\lim_{\theta \to \infty} \omega (\beta, \gamma, \mu + i\theta/\pi, n) = 1.
\]
(26)

Since the value of \( \tilde{I} (\theta, \alpha, N; n) \) is independent of the value of \( N \)
\[
\lim_{\theta \to \infty} \tilde{I} (\theta, \alpha, N; n) = \lim_{\theta \to \infty} \tilde{I} (\theta, \alpha, \infty; n) = 0,
\]
(27)

which then gives the behaviour (20).

With the more accurate evaluation of the asymptotics, the solution of the consistency equations for the first four one-particle and first two two-particle form factors boils down to solving a cubic equation, whose appropriate solution is chosen by the property that it should vanish as \( n \) approaches 1. The expressions for the coefficients are cumbersome, hence we do not list them over here, only the numerical values for \( n = 2, 3, 4 \) in Table 1 and Table 4.

In order to evaluate the von Neumann entropy we also need the asymptotic values of the constants in equations (12) and (13) as \( n \to 1 \). This requires the values
\[
\lim_{n \to 1} (1 - n)K_{11} (\theta; n) = \pi \cosh^2 \frac{\theta}{2},
\]
(28)

and
\[
B_\alpha (\theta; 1) = \frac{1}{2} (\cos (\alpha \pi) - \cosh \theta),
\]
(29)

and the fact that the functions \( f(\theta, \alpha; n) \) all have leading behaviour \( O((n - 1)^0) \) as \( n \) tends to 1. Employing once more the improved asymptotics we have obtained the results of Table 3 and Table 5. It is important to note, that it was crucial to have an explicit solution for the coefficients to extract the \( n \to 1 \) limit, since the fit from different values of \( 1 < n < 2 \) can give misleading coefficients in certain cases.

We point out, that to evaluate integrals of the two-particle form factors, like in eq. (34), in a numerically stable way, we need to regularize the integrals in (15) on the line as was presented.
Table 5: $n \to 1$ leading behaviour of the coefficients of (12) and (13). Note that the precise coefficient of $(n-1)$ in $C_1(n)$ is not given because such term will give no overall contribution to the von Neumann entropy. The same applies to $C_2(n)$.

above for $\tilde{I}(\theta, \alpha; n)$, instead of using the formula where the $f_0(\theta, 0; n)$ factor was pulled out of the expression. The reason is that $\tilde{I}(\theta, \alpha; n)$ diverges around $\theta = 0$, which is compensated by the $f_0(\theta, 0; n)$ term leading to a finite result, however this makes the numerical evaluation unstable around $\theta = 0$.

For the spin field, the structure of the two-particle form factors is very similar to that of the twist field form factors but slightly simpler. The formulae for $F_{\alpha_1\alpha_2}^{\sigma}(\theta)$ were all given in [8, 9]. Here we will only recall

$$F_{11}^{\sigma}(\theta) = \frac{\sin^2 \frac{\pi}{3} \sin^2 \frac{\pi}{5} \sin^2 \frac{\pi}{12}}{B_{\alpha}(\theta; 1)} \frac{Q_{11}(\theta)}{f_{11}(i\pi; 1)},$$

and

$$F_{12}^{\sigma}(\theta) = \frac{\sin^2 \frac{3\pi}{10} \sin^2 \frac{2\pi}{5} \sin^2 \frac{7\pi}{15} \sin^2 \frac{2\pi}{15}}{B_{\alpha}(\theta; 1)} \frac{Q_{12}(\theta)}{f_{12}(i\pi; 1)}.$$

In [9] functions

$$Q_{11}(\theta) = c_{11} \cosh \theta + c_{11}^0, \quad Q_{12}(\theta) = c_{12} \cosh^2 \theta + c_{12}^1 \cosh \theta + c_{12}^0,$$

where computed with

$$c_{11} = -2.093102832, \quad c_{11}^0 = -10.19307727, \quad c_{12} = -7.979022182,$$

$$c_{12}^1 = -71.79206351, \quad \text{and} \quad c_{12}^0 = -70.29218939.$$

1.3 Entanglement Dynamics after a Quench of the Longitudinal Field

Following Eq.(9) of the Letter and the formulae given in [1, 4] we have that the change experienced by the one-point function of the branch point twist field after a quench of the longitudinal field takes the form

$$\langle \Omega | T_n(0, t) | \Omega \rangle = \langle \Omega | T_n(0, 0) | \Omega \rangle_{\text{post}} + \delta_\lambda n \sum_{a=1}^{g} \frac{2}{m_{a,a}} F_{a}^{\sigma} T_{a}^{\sigma} \cos(m_a t)$$

$$+ 2\delta_\lambda \sum_{a,b=1}^{8} \int_{-\infty}^{\infty} \frac{dp_a dp_b \delta(p_a + p_b)}{2\pi e_a e_b} \text{Re} \left[ F_{a}^{ab}(p_a, p_b) F_{a}^{ab*}(p_a, p_b) e^{-i(\epsilon_a + \epsilon_b)t} \right] + O(\delta_\lambda^2).$$
where $\delta \lambda$ is the small change of the QFT coupling constant $\lambda_2 x h \chi$. Here we also used the fact that the one particle form factors are real. We also remind that $\hat{e}_a(p) = \sqrt{m_a^2 + p^2}$, being $m_a$ the post-quench mass of the type-$a$ particle.

From this expression it is relatively straightforward to arrive at the formula for the change of the entanglement entropies given in the Letter, see Eq. (10) there. We know from the definition that

$$S_n(t) := \frac{1}{1-n} \log \left( \epsilon^{\Delta_n} \langle \Omega | \mathcal{T}_n(0, t) | \Omega \rangle \right),$$

therefore

$$S_n(t) - S_n(0) := \frac{1}{1-n} \log \left( \frac{\langle \Omega | \mathcal{T}_n(0, t) | \Omega \rangle}{\langle \Omega | \mathcal{T}_n(0, 0) | \Omega \rangle} \right) = \frac{1}{1-n} \log \left( 1 + \frac{\langle \Omega | \mathcal{T}_n(0, t) | \Omega \rangle - \langle \Omega | \mathcal{T}_n(0, 0) | \Omega \rangle}{\langle \Omega | \mathcal{T}_n(0, 0) | \Omega \rangle} \right),$$

and, at first order in perturbation theory

$$S_n(t) - S_n(0) \approx \frac{1}{1-n} \frac{\langle \Omega | \mathcal{T}_n(0, t) | \Omega \rangle - \langle \Omega | \mathcal{T}_n(0, 0) | \Omega \rangle}{\langle \Omega | \mathcal{T}_n(0, 0) | \Omega \rangle}.$$ (36)

The quantity $\langle \Omega | \mathcal{T}_n(0, 0) | \Omega \rangle_{\text{post}}$, appearing on the RHS of (34) can be also expanded in a power series of $\delta \lambda$. From dimensional analysis and the mass-coupling relation (1) we have that

$$\langle \Omega | \mathcal{T}_n(0, 0) | \Omega \rangle = A_{\tau_n} \lambda_2^{\Delta_{T_n} \sigma_{-2}},$$

where $A_{\tau_n}$ is a non-universal function of $n$. Similarly

$$\langle \Omega | \mathcal{T}_n(0, 0) | \Omega \rangle_{\text{post}} = A_{\tau_n} \left( \lambda_2 + \delta \lambda \right)^{\Delta_{T_n} \sigma_{-2}} = \tau_n \left( 1 + \delta \lambda \frac{\Delta_{T_n}}{\lambda_2^{2-\Delta_{T_n}}} + O(\delta \lambda^2) \right),$$

from (39) and (34) it then follows at first order in $\delta \lambda$

$$S_n(t) - S_n(0) \approx \frac{1}{1-n} \delta \lambda \frac{\Delta_{T_n}}{\lambda_2^{2-\Delta_{T_n}}} + \frac{\delta \lambda n}{1-n} \sum_{a=1}^{8} \frac{2}{m_a^2} F^a_x \hat{T}_a \cos(m_a t),$$

$$+ 2 \delta \lambda n \sum_{a,b=1}^{8} \int_{-\infty}^{\infty} \frac{d p_a d p_b \delta(p_a + p_b)}{2 \pi e_a e_b} \hat{e}_a + \hat{e}_b \Re \left[ \left( F^a_{ab} (p_a, p_b) \right)^* \hat{T}_a \left( p_a, p_b \right) e^{-i \left( \hat{e}_a + \hat{e}_b \right) t} \right] + \cdots,$$

where the form factors of the twist field are normalized by the pre-quench vacuum expectation value $\tau_n$. Analogously, we can normalize the $\sigma$ form factors by the pre-quench expectation value $\bar{\sigma}$ introduced earlier. Generally, this expectation value has the form $\bar{\sigma} = A_{\sigma} \lambda_2^{\Delta_{T_n} \sigma_{-2}}$, where $A_{\sigma}$ is a known constant. Expressing the masses $m_{0,a}$ in the denominators of Eq. (40) in terms of the coupling as well (i.e. recalling Eq. (1)) we end up with

$$S_n(t) - S_n(0) = \frac{1}{1-n} \delta \lambda \frac{\Delta_{T_n}}{\lambda_2^{2-\Delta_{T_n}}} + n A_{\sigma} \sum_{a=1}^{8} \frac{2}{m_a^2} F^a_x \hat{T}_a \cos(m_a t)$$

$$+ 2 n A_{\sigma} \sum_{a,b=1}^{8} \int_{-\infty}^{\infty} \frac{d p_a d p_b \delta(p_a + p_b)}{2 \pi e_a e_b} \hat{e}_a + \hat{e}_b \Re \left[ \left( F^a_{ab} (p_a, p_b) \right)^* \hat{T}_a \left( p_a, p_b \right) e^{-i \left( \hat{e}_a + \hat{e}_b \right) t} \right] + \cdots + O(\delta \lambda^2),$$

(41)
where

\[ C_\sigma = \frac{A_\sigma}{\kappa^2}, \quad (42) \]

is constant featuring in Eq. (10) of the Letter, \( \kappa \) is given in Eq. (1), \( A_\sigma = -1.277(2) \) has been determined for instance in [10], \( r_a \) are the normalized masses defined earlier, and \( \hat{\epsilon}_a \) and \( \hat{p}_a \) are the relativistic energies and momentums (see below Eq. (2)) divided by the mass \( m_{0,1} \). The ellipsis denotes higher particle number terms that are still first order in \( \delta_\lambda \).

In the \( E_8 \) minimal Toda field theory the (post-quench) particle masses are such that \( m_3 > m_1 + m_2 > m_4 > 2m_1 \). For this reason, oscillations coming from the two-particle form factor involving only particle types one and two, will have smaller frequency than those coming from the one-particle form factors of particle type five. Therefore, the six contributions to our expansion which involve the six smallest oscillation frequencies are precisely those coming from the form factors we have reviewed above. It is against these six contributions, that we have compared our numerical results in the Letter. More explicitly, expressing everything in terms of rapidities they are

\[
S_n(t) - S_n(0) = \frac{1}{1 - n \lambda_2} \left[ \frac{\Delta_{\Sigma}}{2 - \Delta_{\Sigma}} + n C_\sigma \sum_{a=1}^{8} \frac{2}{r_a^2} \hat{F}_a^\sigma \hat{F}_a^\Sigma \cos(r_a m_1 t) \right] \\
+ 2n C_\sigma \int_{-\infty}^{\infty} d\theta \frac{1}{2\pi} \frac{1}{\cosh^2 \theta} \operatorname{Re} \left[ (\hat{F}_a^\sigma (2\theta))^* \hat{F}_a^\Sigma (2\theta) e^{-2im_1 t \cosh \theta} \right] \\
+ 2n C_\sigma \int_{-\infty}^{\infty} d\theta \frac{1}{2\pi} \frac{1}{\cosh \theta (\cosh \theta + r_2 \cosh \tilde{\theta})} \times \operatorname{Re} \left[ (\hat{F}_a^\sigma (\theta - \tilde{\theta}))^* \hat{F}_a^\Sigma (\theta - \tilde{\theta}) e^{-im_1 t (\cosh \theta + r_2 \cosh \tilde{\theta})} \right] + \ldots + \mathcal{O}(\delta_\lambda^2),
\]

where

\[
\tilde{\theta} := -\sinh^{-1} \left( \frac{\sinh \theta}{r_2} \right). \quad (44)
\]

The limit \( n \to 1 \) needed to compute the von Neumann entropy can also be performed with the results given in the previous sections. For instance, for the one-particle form factor contributions, we just need to replace the form factors with the functions \( g_i \) defined in (5). This formula will give oscillatory terms of frequencies \( m_1, m_2, m_3, 2m_1, m_4 \) and \( m_1 + m_2 \) and can easily be evaluated numerically. Terms coming from the one-particle form factor contributions give undamped oscillations, whereas contributions from the two-particle form factors, will produce damped oscillations, similar to those found in [4] for a different quench. For large \( t \) it is possible to extract the leading oscillatory part of the two-particle form factor contributions by stationary phase analysis. These terms are suppressed as \( t^{-3/2} \).

Finally, the variation of the expectation value of the spin field after the quench can also be obtained by the same techniques and the expression is almost identical to (34)

\[
\langle \Omega | \sigma(0,t) | \Omega \rangle - \bar{\sigma} = \sigma \frac{\delta_\lambda}{\lambda_2} \left[ \frac{\Delta_{\Sigma}}{2 - \Delta_{\Sigma}} + C_\sigma \sum_{a=1}^{8} \frac{2}{r_a^2} |\hat{F}_a^\sigma|^2 \cos(m_a t) \right] \\
+ 2 C_\sigma \sum_{a,b=1}^{8} \int_{-\infty}^{\infty} \frac{dp_a dp_b}{2\pi \epsilon_a \epsilon_b} \delta(\hat{p}_a + \hat{p}_b) |\hat{F}_a^\sigma(p_a, p_b)|^2 \cos((\epsilon_a + \epsilon_b) t + \ldots) + \mathcal{O}(\delta_\lambda^2).
\]

In Fig. 3 we compare the numerical results for the one-point function of \( \sigma(0,t) \) against the analytical formula (45), incorporating the first four one-particle and the first two two-particle contributions.
2 Transverse Field Quench: Mass Quench in Ising Field Theory

Considering the Ising field theory with $\lambda_2 = 0$, the model can be described by a free Majorana fermion with mass $m_0 = \lambda_1$. In [4] we presented a study of the evolution of entanglement after a mass quench in this model. As explained in [4], the linked cluster expansion of the quench one-point function developed in [11] generalizes to the branch point twist field as

$$
\frac{\langle \Omega | T_n(0, t) | \Omega \rangle}{\langle \Omega | \Omega \rangle} = \tilde{\tau}_n \sum_{k,l=0}^{\infty} D_{2k,2l}(t),
$$

(46)

where $| \Omega \rangle$ is the pre-quench vacuum expressed in the post-quench particle basis as recalled in Eq. (11) of the Letter, $\tilde{\tau}_n$ is the post-quench expectation value of the branch point twist field, $D_{2k,2l}$ is the combination of the expansion coefficients

$$
\frac{\langle \Omega | T_n(0, t) | \Omega \rangle}{\langle \Omega | \Omega \rangle} = \tilde{\tau}_n \sum_{k,l=0}^{\infty} C_{2k,2l}(t),
$$

(47)

and

$$
\langle \Omega | \Omega \rangle = \sum_{q=0}^{\infty} Z_{2q},
$$

(48)

in the form

$$
D_{2k,2l}(t) = \sum_{p=0}^{\min(k,l)} \tilde{Z}_{2p} C_{2(k-p),2(l-p)}(t),
$$

(49)

and $\tilde{Z}_{2p}$ is the inverse of $Z_{2q}$ defined as $\sum_{q=0}^{\infty} Z_{2q} \sum_{p=0}^{\infty} \tilde{Z}_{2p} = 1$. In [4] we showed that (46) was in fact the expansion of the exponential of a Laurent expansion in powers of $t$, with highest power 1. Our proof however was only carried out for terms in the expansion of order $K^2$ where $K(\theta)$ is a known function that enters the definition of $C_{i,j}(t)$. Our aim here is to provide a complete proof of exponentiation. Namely, the statement that (46) is an exponential is a general one and can be shown at all orders in $K(\theta)$. The precise definitions are

$$
\tilde{\tau}_n C_{2k,2l}(t) = \frac{1}{k!l!} \sum_{i_1,...,i_k=1}^{n} \sum_{j_1,...,j_l=1}^{n} \prod_{s=1}^{k} \int_{0}^{\infty} \frac{d\theta'_s}{2\pi} K(\theta'_s)^* e^{2itE(\theta'_s)} \left( \prod_{r=1}^{l} \int_{0}^{\infty} \frac{d\theta_r}{2\pi} K(\theta_r) e^{-2itE(\theta_r)} \right) \times \prod_{s=1}^{k} \langle \theta'_1, -\theta'_1, \ldots, \theta'_k, -\theta'_k | T_n(0, 0) | -\theta_1, \theta_1, \ldots, -\theta_1, 0 \rangle_{j_1j_1\ldots j_lj_l},
$$

(50)

and

$$
Z_{2q} = \frac{1}{(q!)^2} \sum_{i_1,...,i_q=1}^{n} \sum_{j_1,...,j_q=1}^{n} \prod_{s=1}^{q} \int_{0}^{\infty} \frac{d\theta'_s d\theta''_s}{(2\pi)^2} K(\theta'_s)^* K(\theta''_s) \times \prod_{s=1}^{q} \langle \theta'_1, -\theta'_1, \ldots, \theta'_q, -\theta'_q | -\theta_q, \theta_q, \ldots, -\theta_q, 0 \rangle_{j_qj_q\ldots j_qj_q} \quad \text{for} \quad q > 0,
$$

(51)

with $Z_0 = 1$. Combining the form of the expansion with the properties of he form factors such as the crossing relation and the Pfaffian nature of the multi-particle form factors (see [4] for
details), a “connected” expansion for the coefficients \( C_{2k,2l}(t) \) and \( Z_{2q} \) is suggested which reads

\[
C_{2k,2l}(t) = \sum_{\{n_{i,j}\}} \prod_{i,j=0}^{k,l} \frac{\left(C_{2i,2j}(t)\right)^{n_{i,j}}}{n_{i,j}!},
\]

\[
Z_{2q} = \sum_{\{n_{j}\}} \prod_{j=0}^{q} \frac{\left(Z_{2j}\right)^{\tilde{n}_j}}{\tilde{n}_j!},
\]

where the summations go for non-negative integer partitions satisfying the constraints \( \sum_{i,j=0}^{\infty} i \ n_{i,j} = k \), \( \sum_{i,j=0}^{\infty} j \ n_{i,j} = l \), and \( \sum_{i=0}^{\infty} i \tilde{n}_i = q \).

The inverse coefficients \( \tilde{Z}_{2k} \) also admit a connected expansion

\[
\tilde{Z}_{2p} = \sum_{\{\tilde{n}_{i}\}} \prod_{i=0}^{p} \frac{\left(-Z_{2i}\right)^{\tilde{n}_i}}{\tilde{n}_i!},
\]

with the constraint \( \sum_{j=0}^{\infty} j \tilde{m}_j = p \), that we show by evaluating the inverse relation

\[
\sum_{q=0}^{\infty} Z_{2q} \cdot \sum_{p=0}^{\infty} \tilde{Z}_{2p} = \sum_{q=0}^{\infty} \sum_{\{\tilde{n}_{i}\}} \prod_{i=0}^{p} \frac{\left(Z_{2i}\right)^{\tilde{n}_i}}{\tilde{n}_i!} \cdot \sum_{p=0}^{\infty} \sum_{\{n_{j}\}} \prod_{j=0}^{q} \frac{\left(-Z_{2j}\right)^{\tilde{n}_j}}{\tilde{n}_j!}. \tag{55}
\]

Let us reorganize the terms and group them according to number of the function \( K \), i.e. according to the value \( \Delta = k + p \)

\[
\sum_{\Delta=0}^{\infty} \sum_{k=0}^{\Delta} \sum_{\{n_{i}\}} \prod_{i=0}^{k} \frac{\left(Z_{2i}\right)^{\tilde{n}_i}}{\tilde{n}_i!} \sum_{\{n_{j}\}} \prod_{j=0}^{\Delta-k} \frac{\left(-Z_{2j}\right)^{\tilde{n}_j}}{\tilde{n}_j!}. \tag{56}
\]

The sum of the integer partitions \( \{\tilde{n}_i\} \) and \( \{\tilde{m}_j\} \) can be seen as a new partition \( \{\tilde{s}_i\} \) with constraint \( \sum_{i=0}^{\Delta} \tilde{s}_i = \Delta \) that suggest further reorganization of the series to

\[
\sum_{\Delta=0}^{\infty} \sum_{\{\tilde{s}_i\}} \prod_{i=0}^{\tilde{s}_i} \frac{\left(Z_{2i}\right)^{\tilde{s}_i}}{\tilde{s}_i!} \frac{\left(-Z_{2j}\right)^{\tilde{s}_j}}{\tilde{s}_j!} \text{ t}^{-\tilde{s}_i} \text{ t}^{-\tilde{s}_j} \tag{57}
\]

that, according to the binomial theorem, is nothing else but

\[
\sum_{\Delta=0}^{\infty} \sum_{\{\tilde{s}_i\}} \prod_{i=0}^{\tilde{s}_i} \frac{\left[Z_{2i} - Z_{2j}\right]^{\tilde{s}_i}}{\tilde{s}_i!} \tilde{s}_i! = 1, \tag{58}
\]

proving the connected expansion of the inverse coefficients.

Examining the connected coefficients \( C_{2k,2l}(t) \), we see that only diagonal terms, where \( k = l \), are singular, since the successive application of the crossing relation leads to \( C_{2k,2k}(t) \sim Z_{2k} \) in these cases. To have these singularities visible, we reorganize the expansion for \( C_{2k,2l}(t) \) into product of diagonal and non-diagonal coefficients as

\[
C_{2k,2l} = \min(k,l) \sum_{p=0}^{k-p+l-p} \left[ \sum_{\{\tilde{n}_{i}\}} \prod_{i=0}^{p} \frac{\left(C_{2i,2j}(t)\right)^{\tilde{n}_i}}{\tilde{n}_i!} \right] \left[ \sum_{\{n_{i,j}\}} \prod_{i,j=0}^{k-p-l-p} \frac{\left(C_{2i,2j}(t)\right)^{n_{i,j}}}{n_{i,j}!} \right]. \tag{59}
\]
Plugging this back to (49) combining with (54) leads to
\[
D_{2k,2l} = \sum_{q=0}^{\min(k,l)-1} \sum_{p=0}^{\min(k-l,q-q)} \left[ \sum_{\{n_i\}} \prod_{i=0}^{q} \left( -Z_{2i}^c \right)^{\hat{n}_i} \frac{\hat{n}_i!}{m_i!} \right] \times \left[ \prod_{\{m_i\}} \prod_{i,j=0}^{n_{ij}} \frac{\left( C_{2i,2j}^c \right)^{n_{ij}}}{m_{ij}!} \right].
\]
(60)

Introducing the variable \( \Lambda = \frac{p + q}{2} \) we can rearrange the expression to
\[
D_{2k,2l} = \sum_{\Lambda=0}^{\min(k,l)} \left\{ \sum_{\Lambda} \left( \sum_{\{n_i\}} \prod_{i=0}^{2\Lambda} \left( -Z_{2i}^c \right)^{\hat{n}_i} \frac{\hat{n}_i!}{m_i!} \right) \times \left( \prod_{\{m_i\}} \prod_{i,j=0}^{n_{ij}} \frac{\left( C_{2i,2j}^c \right)^{n_{ij}}}{m_{ij}!} \right) \right\}
\]
(62)

By a similar argument as above, we can argue that the terms inside the curly bracket evaluate to
\[
\sum_{\{s_i\}} \prod_{i=0}^{\Lambda} \left( C_{2i,2i}^c - Z_{2i}^c \right)^{\hat{s}_i} \frac{\hat{s}_i!}{s_i!}.
\]
(64)

The combinations \( D_{2i,2j}^c = C_{2i,2i}^c - Z_{2j}^c \) are regular, so are \( D_{2i,2j}^c = C_{2i,2j}^c \) for \( i \neq j \), hence the \( D_{2k,2l}(t) \) also admits a connected expansion that is regular in the form
\[
D_{2k,2l} = \sum_{\{n_{ij}\}} \prod_{i,j=0}^{n_{ij}} \frac{\left( D_{2i,2j}^c \right)^{n_{ij}}}{n_{ij}!}.
\]
(65)

Combining this with (46) leads to the proof of the exponential form of the one-point function
\[
\langle \Omega | T_n(0,t) | \Omega \rangle = \frac{\tilde{\tau}_n}{\langle \Omega | \Omega \rangle} \exp \left[ \sum_{k,l=0}^{\infty} D_{2k,2l}^c \right].
\]
(66)

In the proof we did not use any special property of the branch point twist field form factors other than the crossing relation and the Pfaffian structure for the multi-particle form factors. These are true for other local operators as well, such as the spin field \( \sigma \), hence we showed the full exponentiation of the one-point function of such operators too.

3 Numerical Results

The numerics in the present work were done using the infinite time evolving block decimation algorithm (iTEBD) [12, 13]. Exploiting translational invariance, a general many-body state can be approximated by a matrix product state (written in the canonical form)
\[
|\Psi\rangle = \sum_{\ldots, s_j, s_{j+1}, \ldots} A_{0} \Gamma_{0}^{s_{j}} A_{1} \Gamma_{1}^{s_{j+1}} \ldots |\ldots, s_{j}, s_{j+1}, \ldots\rangle.
\]
(67)
where $\Gamma_{s/o}^e$ are $\chi \times \chi$ matrices associated with the even/odd lattice sites, $\Lambda_{e/o}$ are diagonal $\chi \times \chi$ matrices, with singular values $\lambda_i$ corresponding to the bipartition of the system along even/odd bonds. Expectation values of local operators can be calculated with standard tensor contraction procedures. The singular values on the bonds are the Schmidt coefficients corresponding to the bipartition, meaning that they are the eigenvalues of the reduced density matrix, therefore the entropies can be easily calculated.

The simulation is based on the available code [14]. In our adaptation, both for finding the initial state (pre-quench ground state) using imaginary time evolution, and for the real time evolution we used a fourth order Suzuki–Trotter decomposition [15] of the time evolution operator. For the imaginary time evolution, the time step was set to $\tau = 0.0005$ and we applied $N = 200 000$ Trotter steps, starting the iteration from the fully polarized state. For the post quench real time evolution the time step was set to $\delta t = 0.005$. We kept singular values $\lambda_i > 10^{-12}$ up to a maximal bond dimension which was set to $\chi_{\max} = 300$. Due to the suppression of the entanglement growth shown in Fig. 2 this was sufficient to carry out the simulations.

We run simulations close to the critical point with couplings $h_z = 1$ (the critical value) and $h_x = 0.0005, 0.001, 0.002, 0.003, 0.005$ for quenches with $\delta h_x/h_x = -0.04, 0.05$. The time dependent data has a leading frequency, corresponding to the mass of the lightest quasi-particle $m$. Due to dimensional analysis, rescaling the time with $m = B_{\text{lattice}}(h_x + \delta h_x)^{8/15}$ one can plot the time signal in units of $m^{-1}$, i.e. all the time signals have “leading” frequency $\omega = 1$. For quenches with $\delta h_x/h_x = 0.05$ we obtained the fit $B_{\text{lattice}} \approx 5.42553$, which was used for the $\delta h_x/h_x = -0.04$ quenches as well for consistency, leading to the same period. This procedure is summarized in Fig. 1 for the magnetization. In Fig. 2 we show the result of the rescaling for the von Neumann entropy.

Once all the curves are scaled together, we approximate the data with interpolating curves. This allows us to extrapolate to the scaling limit $h_x \to 0$ up to $mt = 170$. In the extrapolation procedure, first we determine the mass for each $h_x$, clearly having $m \to 0$ for decreasing $h_x$. Together with the time rescaling, this can be also interpreted as sending the lattice spacing $(a)$ to zero, with fixed field theoretical mass $m = 1$. The mass and the lattice spacing always come in dimensionless combinations. We claim that one can extrapolate to the scaling limit using the scaling functions $S_n(a m) = \Delta N / (1 - n) \log(a m) + B(a m)^{1/n} + S_n,\text{scal}.\text{lim.}$ for the entropies and $\sigma(a m) = A(a m)^{1/8} + B a m + \sigma_{\text{scal}.\text{lim.}}$ for the magnetization for any value of $mt$ as in the transverse field case, see [16, 17] and the Appendix of [4]. The fit of the logarithmic behaviour of the von Neumann entropy leads to $c \approx 0.49$ for all times less or equal than $mt = 170$, for both quenches studied, very close to the theoretical value $1/2$. For differences of entropies between different times the universal logarithmic terms cancel, therefore we can perform two parameter fits for $\Delta S_n$ values.

Additionally to the plots in the main text, here we plot our results for the initial time evolution of the magnetization in Fig. 3, and for the third and fourth Rényi entropies in Fig. 4. As in the main text for the von Neumann and the second Rényi entropies, we also had to shift the curves vertically to compensate for possible higher order corrections that are constant in time (such corrections were calculated in [4] for the transverse field quench). The values of the offsets are summarized in Table 6.
Figure 1: The rescaling and mass coupling relation fit, for a quench with $\delta h_x/h_x = 0.05$ for the magnetization difference $\Delta \sigma = \sigma(0,t) - \bar{\sigma}$. Solid curves correspond $h_x = 0.005$, dashed curves to $h_x = 0.005$. In the top plot the time measured in “proper” time, based on the energy scale defined by the lattice Hamiltonian Eq.(1) in the main text, therefore the curve of larger $h_x$ (larger mass) has higher frequency oscillations. In the bottom we rescaled the time to be measured in units of $m^{-1}$, where $m \approx 5.42553(h_x + \delta h_x)^{8/15}$ to have the same frequency and allow for extrapolation.

Figure 2: Results of the rescaling for the von Neumann entropy for $\delta h_x/h_x = 0.05$. In the time frame we have simulation data for extrapolation, there is no visible trace of entanglement growth.
Finally we present some remarks on the suppression of linear growth and on mass shifts beyond first order perturbation theory. In [18], was determined up to $\mathcal{O}(\delta^2)$ a perturbative expansion.
for the pre-quench state $|\Omega\rangle$ in the eigenstates of the post-quench Hamiltonian $H_{\text{post}}$ for the $E_8$ field theory; cf. Eq. (5) of our Letter. Of particular importance to estimate the rate of entanglement growth are the overlaps of pairs with zero momentum [19]

$$K_{ab}(\theta) := \langle \text{post}; a, b | \theta, -\theta | \Omega \rangle; \quad a, b = 1, \ldots, 8. \quad (68)$$

An interesting feature of these functions can be inferred from plots presented in Section 4 of [18]. One observes that the value of $|K_{11}(\theta_*)|$ where $\theta_*$ is the value of $\theta$ for which $|K_{11}(\theta)|$ is maximal, is of order $10^{-3}$ for $\delta\lambda/\lambda_2 = 0.05$. In addition, $|K_{11}(\theta)|$ represents the largest particle overlap, so the maxima of other functions $K_{ab}(\theta)$ where $a, b$ are not both 1, are generally at least one order of magnitude smaller. If we compare these orders of magnitude with the same values for the function $|K(\theta)|$ involved in the study of the Ising field theory mass quench [11], we see that $|K(\theta_*)| \approx 10^{-2}$ for the same quench, so roughly one order of magnitude larger. Since both the entanglement slope [4] and the higher order mass corrections [20] are expected to be proportional to $|K_{ab}(\theta)|^2$, for small quenches in the $E_8$ field theory, they are small and not visible on the timescales accessible with iTEBD. In order to further support these claims we have run an additional simulation for a quench of $h_x = 0.005$ and $\delta h_x = 0.005$ and very large times. The resulting time evolution is plotted in Fig. 5. The time rescaling was carried out using the same mass coupling relation as for small quenches. In this way the smallest frequency of the oscillations is close to one, within the resolution provided by the finite time window. This implies that even for a large quench, $\delta h_x/h_x = 1$, renormalization of the frequencies is absent. It is worth mentioning that the amplitudes of the oscillations are not predictable from a first order perturbative calculation. However, the numerical results certainly suggest that the oscillations in the entanglement entropy are not suppressed by higher order in perturbation theory. It is hard to assess whether the entropy will eventually grow linearly at large time from the numerical data, though failure to relax toward equilibrium is clear. Finally we note that there is a very low frequency modulation of the signal, which turns out to be related to the frequency $2m_1 - m_3$. 

![Figure 5: Time evolution of entanglement entropy for a large quench $\delta h_x/h_x = 1.0$ with $h_x = 0.005$. The data suggest a slight drift in time of the entanglement entropy with oscillations present for large times as well. The low frequency modulation is related to the frequency $2m_1 - m_3$.](image)
