E-mail: andreas.ringwald@desy.de

Existing and planned observatories for cosmic neutrinos open up a huge window in energy from $10^7$ to $10^{17}$ GeV. Here, we discuss in particular the possibilities to use extremely energetic cosmic neutrinos as a diagnostic of astrophysical processes, as a tool for particle physics beyond the Standard Model, and as a probe of cosmology.

1. Introduction

We are living in exciting times for extremely high energy cosmic neutrinos (EHECν’s). Existing observatories, such as AMANDA, ANITA-lite, BAIKAL, FORTE, GLUE, and RICE have recently put restrictive upper limits on the neutrino flux in the energy region from $10^7$ to $10^{17}$ GeV (cf. Fig. 1). Furthermore, recent proposals for larger EHECν detectors, such as ANITA, EUSO, IceCube, LOFAR, OWL, PAO, SalSA, WSRT, together with conservative neutrino flux predictions from astrophysical sources of the observed cosmic rays (CR’s), such as active galactic nuclei, offer credible hope that the collection of a huge event sample above $10^7$ GeV may be realized within this decade (cf. Fig. 1). This will provide not only important information on the astrophysical processes associated with the acceleration of CR’s, but also an opportunity for particle physics beyond the reach of the Large Hadron Collider (LHC). There is even the possibility of a sizeable event sample above $10^{11}$ GeV, with important consequences for cosmology. The corresponding neutrino fluxes may arise from the decomposition of topological defects – relics of phase transitions in the very early universe – into their particle constituents. Moreover, it may be possible to detect the cosmic neutrino background via absorption features in these neutrino spectra. In this contribution, we will have a closer look at these exciting opportunities.

*Talk presented at the ARENA Workshop, DESY, Zeuthen, Germany, May 17-19, 2005.
2. EHEC$\nu$'s as a diagnostic of astrophysical processes

Neutrinos with energies $\lesssim 10^{12}$ GeV propagate essentially without interaction between their source and Earth. Hence, they are a powerful probe of high energy astrophysics, in particular of the conjectured acceleration sites of the CR's, notably active galactic nuclei (AGN). A paradigm for the acceleration mechanism in the jets of these AGN's is shock acceleration. Protons and heavier nuclei are confined by magnetic fields and accelerated through repeated scattering by plasma shock fronts. Inelastic collisions of the trapped protons with the ambient plasma produces pions and neutrons, the former decaying into neutrinos and photons, the latter eventually diffusing from the source and decaying into CR protons (cf. Fig. 2 (left)).

A quite conservative estimate of the flux of neutrinos from such astro-
physical sources can be made as follows\textsuperscript{14}. Assuming that the sources are optically thin, i.e. the neutrons can escape, one may determine the neutron emissivity at the sources from the observed CR spectra\textsuperscript{17}, taking into account propagation effects, in particular $e^+e^-$ and pion production through inelastic scattering off the CMB photons. Figure 2 (right) illustrates that both the AGASA and the HiRes data in the $10^{8.6-11}$ GeV range can be fitted nicely under the assumption of a simple power law neutron injection emissivity, $\propto E_i^{-2.5}(1+z)^{3.5}$, of the extragalactic sources, supporting the recent proposal towards a low transition energy, $\sim 10^{8.6}$ GeV, between galactic and extragalactic cosmic rays\textsuperscript{22}, which is also sustained by chemical composition studies of HiRes data\textsuperscript{25}. The neutron injection emissivity is simply related to the neutrino emissivity, and the latter can be translated easily into an expected neutrino flux at Earth. It should be detected very soon, if not already with AMANDA-II, then at least with IceCube (cf. Fig. 1), which therefore can provide significant clues in demarcating the cosmic ray galactic/extragalactic crossover energy\textsuperscript{14}. Although the cosmogenic neutrino flux from the inelastic interactions with the CMB photons
5. The dashed-dotted lines indicate the sensitivity (95% CL, for $\sigma_{\nu N}^{tot} < 4$ mb) of PAO in 10 yr of operation assuming zero events observed above SM background (circles PJ, triangles FKRT). For comparison, also shown is the SM total (charged current and neutral current) $\nu N$ inelastic cross section.

starts to dominate over the neutrino flux from optically thin cosmic ray sources at energies above a few EeV, it appears to be hard to detect with the EHEC$\nu$ detectors operating in the next decade (cf. Fig. 1).

3. EHEC$\nu$’s and physics beyond the Standard Model

Cosmic neutrinos with energies $E_\nu$ above $10^8$ GeV probe neutrino-nucleon scattering at center-of-mass (c.m.) energies above

$$\sqrt{s_{\nu N}} \equiv \sqrt{2m_N E_\nu} \simeq 14 \text{ TeV} \left( E_\nu/10^8 \text{ GeV} \right)^{1/2},$$

(1)

beyond the proton-proton c.m. energy $\sqrt{s_{pp}} = 14$ TeV of the LHC, and Bjorken $x \equiv Q^2/(y s_{\nu N})$ values below

$$x \simeq 2 \times 10^{-4} \left( Q^2/m_W^2 \right) (0.2/y) \left( 10^8 \text{ GeV}/E_\nu \right),$$

(2)

where $Q^2$ is the momentum transfer squared, $m_W \simeq 80$ GeV the $W$-boson mass, and $y$ the inelasticity parameter. Under these kinematical conditions, the predictions for $\nu N$ scattering from the perturbative Standard Model...
(SM) are quite safely under control (cf. Fig. 3 (left)), notably thanks to the input from measurements of deep-inelastic ep scattering at HERA\textsuperscript{31,32}. This makes it possible to search for enhancements in the $\nu N$ cross section due to physics beyond the (perturbative) SM, such as electroweak sphaleron\textsuperscript{33} (non-perturbative $B+L$ violation), or Kaluza-Klein, black hole, $p$-brane, or string ball production in TeV scale gravity models\textsuperscript{34}.

Since the rate of neutrino-initiated showers is proportional to integrated flux times cross section, the non-observation of quasi-horizontal or deeply-penetrating neutrino-induced air showers as reported by, e.g., Fly’s Eye\textsuperscript{35}, AGASA\textsuperscript{36}, and RICE\textsuperscript{6} can be turned into an upper bound on the neutrino nucleon cross section if a certain prediction for the neutrino flux is exploited\textsuperscript{37,38}. This is exemplified in Fig. 3 (right), which displays the limits on $\sigma_{\nu N}$ from the RICE search results on contained showers\textsuperscript{40}, for two different assumptions about the EHEC$\nu$ flux. These bounds are considerably higher than the SM cross section, albeit in the post-LHC energy region. PAO will be able to improve these limits by one order of magnitude\textsuperscript{40}.

![Figure 4](image-url)  
Figure 4. The range of the cross section within the 99%, 95% and 90% CL required for a successful strongly interacting neutrino scenario\textsuperscript{42}. The lines are theoretical predictions of an enhancement of the neutrino-nucleon cross-section by electroweak sphalerons\textsuperscript{43,44} (short-dashed), $p$-branes\textsuperscript{45} (long-dashed) and string excitations\textsuperscript{46} (dotted).
The bounds exploiting searches for deeply-penetrating particles are typically applicable as long as \( \sigma_{\nu N} \lesssim 0.5 \div 1 \text{ mb} \). Models with even higher and more speculative cross sections, \( \gtrsim 1 \div 10 \text{ mb} \), such as electroweak sphaleron production, brane production, or string resonance production, qualify as strongly interacting neutrino scenarios, according to which the mysterious EHECR beyond the predicted GZK cutoff at \( E_{\text{GZK}} \simeq 4 \times 10^{10} \text{ GeV} \) (cf. Fig. 2 (right)) are initiated by cosmogenic neutrinos. Figure 4 illustrates that a combined fit of the existent data on vertical showers by AGASA and HiRes, as well as of the search results on weakly interacting particles of AGASA and RICE, requires a steep increase within one energy decade around \( E_{\text{GZK}} \) by four orders of magnitude—an enhancement which has indeed been proposed within some extensions of the (perturbative) SM.

We have emphasized here the current constraints from EHEC\(\nu\) on physics beyond the SM. A more detailed account of the particle physics reach of the planned EHEC\(\nu\) observatories can be found elsewhere.

4. EHEC\(\nu\)’s as a tool to study big bang relics

The existence of topological stable solutions of the field equations (topological defects) is a generic prediction of symmetry breaking (SB) in Grand Unified Theories (GUT’s) and occurs even at the fundamental level in String Theory in the form of F- and D-strings. Specifically, \( G \to H \times U(1) \) SB leads to monopoles, \( U(1) \) SB to ordinary or superconducting strings, and \( G \to H \times U(1) \to H \times Z_N \) SB to monopoles connected by strings, e.g. necklaces in case of \( N = 2 \). Such topological defects may be produced through non-thermal phase transitions during preheating after inflation. Their superheavy constituents \( X \), often gauge or Higgs bosons with masses \( m_X \sim 10^{12\div16} \text{ GeV} \), may be liberated on various occasions, e.g. through repeated self-intersections of strings, through annihilation of monopole antimonopole pairs etc., and rapidly decay into stable SM particles, under which we readily find EHEC\(\nu\)’s with energies up to \( \sim 0.05 \) \( m_X \). The corresponding fragmentation spectra are meanwhile worked out very accurately via Monte Carlo generators or via DGLAP evolution from experimentally determined initial distributions at the scale \( m_Z \) to the ones at \( m_X \). The injection rate, which determines in particular the overall normalization of the neutrino flux, depends on cosmic time \( t \) in the form \( \dot{\nu}_X = \kappa m_X^p t^{-4+p} \), where \( \kappa \) and \( p \) are dimensionless constants depending on the specific scenario.

For a wide range of overall flux normalizations, the upcoming EHEC\(\nu\) observatories seem to be sensitive enough to obtain, within the next decade,
sizeable event rates from topological defects\textsuperscript{16} (cf. Fig. 5). Note, that, for the first time in cosmic particle physics, the GUT energy scale can be directly probed. Clearly, a precise measurement of the neutrino spectrum from topological defects would have a strong impact on particle physics and cosmology. Its mere existence would signal the existence of topological defects as relics from early phase transitions after inflation. The high end of the spectrum directly reveals the mass of the $X$ particles, and its shape entails detailed information on the particle content of the desert, on the Hubble expansion rate, and on the big bang relic neutrino background. Indeed, as illustrated in Fig. 5, the resonant annihilation of the neutrinos from $X$ particle decays with big bang relic neutrinos would leave its imprints as absorption dips in the measured spectrum\textsuperscript{56}. Such a measurement would not only shed light on the existence and the spatial distribution\textsuperscript{57} of the cosmic neutrino background, but would also give important information on the neutrino masses\textsuperscript{58}, since the dips occur around the resonance energies $E_{\nu_i}^{\text{res}} = 4 \times 10^{21} \text{ eV} (1 \text{ eV}/m_\nu)$). Note, that, along with a prediction of absorption dips, there goes a prediction of emission features\textsuperscript{59} – protons and photons from hadronic $Z$-decay (“$Z$-bursts”) – which may appear as
a CR flux recovery beyond \( E_{\text{GZK}} \) and be measured by EUSO, OWL, or LOFAR\(^{16}\).

5. Conclusions

The future seems bright in extremely high energetic neutrinos. There are many observatories under construction, whose combined sensitivity ranges from \( 10^7 \) to \( 10^{17} \) GeV, the energy scale of Grand Unification. In the likely case that appreciable event samples are collected in this energy range, we can expect a strong impact on astrophysics, particle physics, and cosmology.
