A nonperturbative interaction of an electronic system with a laser field can substantially modify its physical properties. In particular, in two-dimensional (2D) materials with a lack of inversion symmetry, the achievement of a regime of strong light-matter coupling allows direct optical tuning of the strength of the Rashba spin-orbit interaction (SOI). Capitalizing on these results, we build a theory of the dynamical conductivity of a 2D electron gas with both Rashba and Dresselhaus SOIs coupled to an off-resonant high-frequency electromagnetic wave. We argue that strong light-matter coupling modifies qualitatively the dispersion of the electrons and can be used as a powerful tool to probe and manipulate the coupling strengths and adjust the frequency range where optical conductivity is essentially nonzero.

DOI: 10.1103/PhysRevB.94.161404

Introduction. Since the appearance of the pioneering works on spintronics, followed by unprecedented research progress in the field [1], there has been tremendous interest in studying spin-orbit coupled systems. This is mainly motivated by the possibility to use spin-orbit interactions (SOIs) for the design of prospective nanoelectronic devices [2] where the spin of a spin-orbit coupled systems. This is mainly motivated by the field [1], there has been tremendous interest in studying spintronics, followed by unprecedented research progress on the crystalline lattice itself (the so-called Dresselhaus term [3]) or structural asymmetry of the quantum well (the Rashba term [4]). While the strength of the Dresselhaus term is determined exclusively by the material and geometry of the structure, the strength of the Rashba term can be tuned by application of a gate voltage, which opens a way for the design of various spintronic components including Datta-Das spin field-effect transistors [5].

Meanwhile, the search for alternative ways to manipulate spin-orbit coupling still attracts considerable attention. It was recently proposed that the latter can be achieved by coupling of a 2D electron system with a strong off-resonant electromagnetic field (dressing field) [6], when no real absorption of the wave takes place but the spectrum of the system is changed. This corresponds to the so-called regime of strong light-matter coupling. The resulting dispersion renormalization was recently studied for the electrons in bulk semiconductors [7,8], quantum wells [9–12], and graphene [13–19]. The dressing field also has a profound impact on the transport properties of low-dimensional electronic structures. In particular, it leads to an increase of dc conductivity of a two-dimensional electron gas (2DEG) and suppresses the effect of weak localization [12].

Effective time-independent Hamiltonian. We consider a spin-orbit coupled 2DEG in which the electrons are restricted to move within a plane perpendicular to the z axis irradiated by an external electromagnetic wave propagating perpendicular to the interface, \( \mathbf{E} = E_0 \cos \Omega t \), where \( E_0 = |E_0| \) is an amplitude of the wave and \( \Omega \) is frequency. Periodic time dependence is characterized by a symmetry operation that corresponds to a translation by a period of a driving field, and Floquet quasienergies [25–27] describe the total phase shifts the quantum system picks up, evolving over a period. As long as the frequency of the irradiating field is far from the resonant frequencies of electronic interband transitions, so that interband absorption does not happen, and is high enough to satisfy a condition \( \Omega \tau \gg 1 \) (where \( \tau \) stands for the relaxation time of a bare Hamiltonian) the problem can be mapped to an effective time-independent model in which the parameters of the undriven Hamiltonian are renormalized by the field. In our further discussion we focus on the nonlinearly dressed field only, \( E_0 = -E_0 \delta \).

Effective time-independent Hamiltonian. We start our analysis with the Hamiltonian of a spin-orbit coupled 2DEG,

\[
H = \frac{p_x^2 + p_y^2}{2m} + \alpha (p_x \sigma_z - p_y \sigma_x) + \beta (p_x \sigma_x - p_y \sigma_y),
\]

where \( m \) is the electron mass, \( \alpha \) and \( \beta \) are the Rashba and Dresselhaus terms, respectively, and \( \sigma_i \) are Pauli spin matrices. The field \( \mathbf{E} \) induces a dynamical gap opening and the resulting photocurrent can flow without any applied bias voltage [21].
where $\sigma = (\sigma_x, \sigma_y, \sigma_z)$ is a vector of Pauli matrices acting in spin space, and constants $\alpha$ and $\beta$ characterize the strengths of Rashba and Dresselhaus couplings, respectively. This Hamiltonian describes, for example, an InAs-based quantum well grown in the [001] direction [28]. The eigenstates of this Hamiltonian are purely determined by the electron momentum $\mathbf{p} = (p_x, p_y)$ and chirality of the spin branches. In the presence of an external electromagnetic field the Hamiltonian acquires a time-dependent term via a canonical replacement $\mathbf{p} \rightarrow \mathbf{p} - e\mathbf{A}(t)/c$, which originates from a minimal coupling to the field, where $\mathbf{A}(t) = -c \int_0^t \mathbf{E}(t') dt'$ (here, $c$ is the speed of light).

Performing unitary transformation with a matrix,

$$U(t) = \frac{1}{\sqrt{2}} \begin{pmatrix} e^{-i\frac{\gamma_p}{2}\Omega_1 t} e^{-i\frac{\gamma_e}{2}\Omega_1 t} & \alpha_x e^{i\frac{\gamma_p}{2}\Omega_1 t} e^{i\frac{\gamma_e}{2}\Omega_1 t} \\ e^{i\frac{\gamma_p}{2}\Omega_1 t} e^{i\frac{\gamma_e}{2}\Omega_1 t} & e^{i\frac{\gamma_p}{2}\Omega_1 t} e^{i\frac{\gamma_e}{2}\Omega_1 t} \end{pmatrix},$$

(2)

where $\gamma = eE_0 \sqrt{\alpha^2 + \beta^2/(\hbar \Omega_1^2)}$ is dimensionless field-matter coupling and $\tan \xi = \beta/\alpha$, and keeping zeroth-order harmonics [29] in the Floquet expansion only (which is possible for off-resonant external fields), we can reduce the problem to an effective time-independent Hamiltonian that resembles a bare Hamiltonian with effective anisotropic Rashba and Dresselhaus couplings renormalized by the field,

$$\tilde{H} = \frac{p_x^2 + p_y^2}{2m} + \left( \alpha_x p_x + \beta_x p_y \right) \sigma_x - \left( \alpha_y p_x + \beta_y p_y \right) \sigma_y,$$

(3)

where Rashba

$$\alpha_x = \alpha \left[ 1 - \frac{\alpha^2 - \beta^2}{\alpha^2 + \beta^2} (1 - J_0(2\gamma)) \right], \quad \alpha_y = \alpha,$$

(4)

and Dresselhaus-type couplings

$$\beta_x = \beta \left[ 1 + \frac{\alpha^2 - \beta^2}{\alpha^2 + \beta^2} (1 - J_0(2\gamma)) \right], \quad \beta_y = \beta.$$  

(5)

In expressions (4) and (5), $J_0(2\gamma)$ is the zeroth-order Bessel function of the first kind. Thus, the off-resonant electromagnetic field provides a versatile tool to tune the corresponding spin-orbit strengths. One can easily verify that the dispersion relations of dressed electrons and corresponding eigenstates (see Fig. 1 to observe renormalization due to an external field) of the Hamiltonian $\tilde{H}$ are determined by

$$\varepsilon_{\mathbf{k} \lambda} = \frac{p_x^2}{2m} + \lambda p \Delta(\theta), \quad |\mathbf{p}\lambda\rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} \lambda e^{-i\Phi} \\ \lambda e^{i\Phi} \end{pmatrix},$$

(6)

where $\tan \Phi = (\alpha_x \cos \theta + \beta_x \sin \theta)/(\alpha_x \sin \theta + \beta_x \cos \theta)$, the chirality index is denoted by $\lambda = \pm 1$, and the anisotropic spin splitting is defined by

$$\Delta(\theta) = \sqrt{\left( \alpha_x \cos \theta + \beta_x \sin \theta \right)^2 + \left( \alpha_x \sin \theta + \beta_x \cos \theta \right)^2}.$$  

(7)

It is worth noting that the angle $\tan \theta = p_y/p_x$, while for a system doped up to $E_F > 0$ and a concentration of charge carriers $n$,

$$E_F = \frac{\pi n \hbar^2}{m} - \frac{m(\alpha_x^2 + \alpha_y^2 + \beta_x^2 + \beta_y^2)}{2},$$

(8)

can be tuned by changing the field parameters. Note that the expression for $\tilde{H}$ and consequent relations are formally true as long as the argument of $J_0(2\gamma)$ is far from the nulls of the Bessel function [29].

**Optical conductivity.** The effects of electromagnetic dressing can be experimentally explored by studying the optical response of the system in a pump-probe geometry. In this case, a sample is excited by a continuous-wave highly intense laser (pump) while the second pulse (probe) is used for characterization of the excited states of the hybrid light-matter system. The proper description of experimentally relevant signals requires an adequate understanding of how an electromagnetic pulse of finite length propagates through a material which is driven out of equilibrium. If the probing field is weak enough, its effect shows up as a linear response of the current to the external field $\delta j_\alpha(\omega) = \sigma_{\alpha\beta}(\omega) \delta E_\beta(\omega)$, where the subscripts stand for Cartesian components of the vectors and tensors. It is worth noting that only the probe field is assumed to be weak, whereas no assumptions have been made about the strength of the pump field. Along with a standard Drude peak, the conductivity of a spin-orbit coupled system picks up an extra term determined by the Kubo formula. For a probing field of frequency $\omega$ it can be evaluated as follows,

$$\sigma_{\alpha\beta}(\omega) = \frac{1}{\hbar \omega} \int_0^\infty dt \langle \hat{j}_\alpha(t), \hat{j}_\beta(0) \rangle e^{i(\omega + i\delta)t},$$

(9)

where $\delta$ is a positive infinitesimal constant introduced to guarantee the convergence of the integral. The angular brackets stand for quantum and thermal averaging.

With the help of the Hamiltonian $\tilde{H}$ we can estimate the current operators,

$$\mathbf{j} = \nabla_p \tilde{H} = -e \begin{pmatrix} p_x \\ p_y \end{pmatrix} - e \sigma_x \begin{pmatrix} \beta_x \alpha_y \\ \alpha_x \beta_y \end{pmatrix} + e \sigma_y \begin{pmatrix} \alpha_x \alpha_y \\ \beta_x \beta_y \end{pmatrix}.$$  

(10)
becomes isotropic. Analytical formulas for Re \( \Re \sigma_{xx}(\omega) \) and Re \( \Re \sigma_{xy}(\omega) \) plotted for different values of the field-matter coupling \( \gamma = \epsilon E_0 \sqrt{a^2 + b^2}/(\hbar \Omega^2) \) with a fixed ratio \( \beta/\alpha = 0.125 \). The red solid line specifies the case with no dressing. An increase in the field-matter coupling results in the frequency domain being broadened and shifting slightly past the original position. The dashed area in the inset to the top panel shows the integration area in (11), while the solid line specifies the case with no dressing. An increase in the field-matter coupling leads to a momentum-independent \( \omega > \omega_0 \) and \( \omega = \omega_0 \).

Without loss of generality, in the following we assume \( \omega > 0 \), and after quite straightforward algebra we obtain [29]

\[
\Re \sigma_{ab}(\omega) = \frac{e^2 (\alpha_x \alpha_y - \beta_x \beta_y)^2}{4 \pi \hbar^2} \int \frac{d^2 p}{\Delta^2(\theta)} \times \left( \begin{array}{cc} \sin^2 \theta & -\sin \theta \cos \theta \\ -\sin \theta \cos \theta & \cos^2 \theta \end{array} \right) \times \delta(\epsilon_{p+} - \epsilon_{p-} - \hbar \omega). \tag{11}
\]

Expression (11) clearly manifests that the conductivity due to spin-orbit coupling disappears for \( |\alpha| = |\beta| \). In fact, in this case a delicate interplay between the Dresselhaus and the Rashba couplings leads to a momentum-independent eigenspinor [30,31], and the conductivity of the system becomes isotropic. Analytical formulas for Re \( \Re \sigma_{ab}(\omega) \) are listed in Ref. [29]. In contrast to a pure Rashba or Dresselhaus system, the frequency range where Re \( \Re \sigma_{ab}(\omega) \neq 0 \) is more broadened \( \omega_- \leq \omega \leq \omega_+ \) (Fig. 2), where

\[
\hbar \omega_{\pm} = \hbar \Omega_{\pm}(\Delta_{\pm}), \tag{12}
\]

and we have defined the functions

\[
\hbar \Omega_{\pm}(\Delta(\theta)) = 2 \Delta(\theta)(\sqrt{m^2 \Delta^2(\theta) + 2m E_F} \pm m \Delta(\theta)), \tag{13}
\]

which determine the integration area \( \Omega_{\pm}(\theta) \leq \omega \leq \Omega_{\pm}(\theta) \) over the polar angle \( \theta \), while \( \Delta_{\pm} \) denote the maximum and minimum of \( \Delta(\theta) \), respectively. The energies \( \hbar \omega_{\pm} \) correspond to the minimum and the maximum photon energy required to induce the optical transitions between the initial \( \lambda = -1 \) and final \( \lambda = +1 \) subbands and coincide with the absorption edges of the spectrum.

Results and discussion. Close inspection of formulas (12) reveals that the presence of an intense electromagnetic field allows one to optically tune the values of \( \hbar \omega_{\pm} \). The results of the numerical calculations of conductivity (11) are shown in Fig. 2. We used the parameters that are experimentally accessible in InAs-based quantum wells grown in the [001] direction [28,32,33], \( m = 0.055 m_e \), where \( m_e \) is the free-electron mass, \( \alpha = 1.6 \times 10^{-9} \text{ eV cm} \), \( \beta = 0.125 \alpha \), \( n = 5 \times 10^{11} \text{ cm}^{-2} \), and \( \gamma = 0, 0.3, 0.6, \) and 0.9. It can be seen that Re \( \Re \sigma_{ab}(\omega) \) is nonzero only in a well-defined interval of frequencies, \( \omega_- < \omega < \omega_+ \), and both \( \omega_+ \) and \( \omega_- \) decrease as functions of dimensionless field-matter coupling \( \gamma \) and the range of the frequencies where the real part of the conductivity is nonzero becomes broadened. The major factor that determines this interval is related to the Fermi surface topology and explains the possible excitation energies of electron-hole pairs (electron-hole continuum). Note that for \( \gamma = 0 \) our results coincide with those reported in previous studies [22].
The two peaks in Figs. 2 and 3 correspond to electronic excitations involving states with allowed wave vectors exactly at $\hbar \omega_a = \hbar \Omega_1 (\Delta_-)$ and $\hbar \omega_b = \hbar \Omega_2 (\Delta_+)$ (featured in the inset to the Fig. 2), provided $\omega_- < \omega_b < \omega_a < \omega_+$. This is in huge contrast to the results of a pure Rashba or Dresselhaus system for which $\text{Re } \sigma_{xx}(\omega) = e^{2}(J_{0}(2\gamma))/(16\pi \hbar)$, and $\text{Re } \sigma_{yy}(\omega) = e^{2}/(16\pi \hbar J_{0}(2\gamma))$, in the finite frequency range determined by $|\hbar \omega - 2\alpha \sqrt{m^2 a^2 + 2m E_F}| \lesssim 2ma^2$.

One can also observe that the lower peak of the components of the conductivity tensor $\text{Re } \sigma_{ab}(\omega)$ at $\omega = \omega_a$ moves towards $\omega_-$ with an increase of $\gamma$ (see Fig. 2). This effect becomes even more pronounced when the ratio $\beta/\alpha$ grows. Interestingly, $\text{Re } \sigma_{xx}(\omega)$ reaches maximal value in the absence of a dressing field and becomes suppressed with an increase of $\gamma$. This is in contrast to the behavior of $\text{Re } \sigma_{yy}(\omega)$, which is shown to take the lowest value in the absence of the field and gains a maximum value at $\omega_-$ with increasing $\gamma$ (not shown).

Contrary to a pure Rashba or Dresselhaus material, in which it requires a circularly polarized field [34], in a biased two-dimensional electron gas, the presence of both couplings leads to the emergence of Hall-type conductivity of the charge carriers, even in the absence of an external magnetic field [35] (see also Ref. [29]). Results presented in Fig. 2 show that the Hall-type conductivity is also quite sensitive to the dressing field. The off-diagonal components of the frequency-dependent conductivity tensor can be accessed, e.g., via measurements of the Faraday rotation angle, which for sufficiently thin films is proportional to $\sigma_{xy}(\omega)$ (see, e.g., Ref. [36]).

It should be noted that the modification of the dynamical conductivity by a dressing field allows for an experimental determination of the relative strength of the spin-orbit coupling $\beta/\alpha$. The current methods include photocurrent measurements [28,37] or optical monitoring of electron spin precession [38], or persistent charge and spin current measurements in a mesoscopic ring [39]. We propose to extract $\alpha$ and $\beta$ from spectroscopic experiments in the pump-probe regime. Based on the theory developed in this Rapid Communication, one can show that

$$E_F = \left( p_0^2 - \sqrt{p_0^2 - A m^2} \right)/(4m),$$

and

$$|\alpha^2 - \beta^2| = \frac{B}{8m E_F J_0(2\gamma)},$$

$$\alpha^2 + \beta^2 = \frac{A J_0(2\gamma) + 2J^2_0(2\gamma) + 8B^2(1 - J^2_0(2\gamma))}{32m E_F J_0(2\gamma)},$$

where $p_0 = \sqrt{2\pi n \hbar^2}$ is the Fermi momentum of a spin-degenerate two-dimensional electron gas, $A = \hbar^2 (\omega_- \omega_a + \omega_b \omega_+)$, and $B = \hbar^2 \sqrt{\omega_- \omega_a \omega_b \omega_+}$. The parameters $\omega_\pm, \omega_a$, and $\omega_b$ can be extracted implicitly from the experimentally measured dynamical conductivity curves for various light-matter coupling parameters $\gamma$ (Fig. 3).

Conclusions and outlook. In this Rapid Communication we have provided a systematic and self-contained analysis of the transport properties of a dressed 2D electron system with simultaneous Rashba and Dresselhaus SOIs. We showed that strong light-matter coupling leads to renormalization of the spectrum of the system, which results in a dramatic modification of the dynamical conductivity of a system. In particular, we demonstrated that the frequency range where the conductivity is essentially nonzero can be tuned by properly adjusting the parameters of the dressing field. Moreover, we proposed a way to define independently the constants of Rashba and Dresselhaus SOIs in all-optical measurements.
