In this article we investigate the properties of the FLRW flat cosmological models in which the cosmic expansion of the Universe is affected by a dilaton dark energy (Liouville scenario). In particular, we perform a detailed study of these models in the light of the latest cosmological data, which serves to illustrate the phenomenological viability of the new dark energy paradigm as a serious alternative to the traditional scalar field approaches. By performing a joint likelihood analysis of the recent supernovae type Ia data (SNIa), the differential ages of passively evolving galaxies, and the Baryonic Acoustic Oscillations (BAOs) traced by the Sloan Digital Sky Survey (SDSS), we put tight constraints on the main cosmological parameters. Furthermore, we study the linear matter fluctuation field of the above Liouville cosmological models. In this framework, we compare the observed growth rate of clustering measured with those predicted by the current Liouville models. Performing a $\chi^2$ statistical test we show that the Liouville cosmological model provides growth rates that match sufficiently well with the observed growth rate. To further test the viability of the models under study, we use the Press-Schechter formalism to derive their expected redshift distribution of cluster-size halos that will be provided by future X-ray and Sunyaev-Zeldovich cluster surveys. We find that the Hubble flow differences between the Liouville and the $\Lambda$CDM models provide a significantly different halo redshift distribution, suggesting that the models can be observationally distinguished.

I. INTRODUCTION

The comprehensive study carried out in recent years by the cosmologists has converged towards a cosmic expansion history that involves a spatially flat geometry and a recent accelerating expansion of the Universe (see \textsuperscript{1–8} and references therein). From a theoretical point of view, an easy way to explain this expansion is to consider an additional energy component, usually called dark energy (hereafter DE) with negative pressure, that dominates the Universe at late times. The simplest DE candidate corresponds to the cosmological constant (see \textsuperscript{9–11} for reviews). Indeed the so-called spatially flat concordance $\Lambda$CDM model, which includes cold dark matter (CDM) and a cosmological constant ($\Lambda$), fits accurately the current observational data and thus it is an excellent candidate to be the model which describes the observed Universe.

Nevertheless, the identification of $\Lambda$ with the quantum vacuum has brought another problem: the estimate of theoretical physicists that the vacuum energy density should be 120 orders of magnitude bigger than the measured $\Lambda$ value. This is the “old” cosmological constant problem (CCP) \textsuperscript{9}. The “new” problem \textsuperscript{10} asks why is the vacuum density so similar to the matter density just now? Many solutions to both problems have been proposed in the literature \textsuperscript{12–14}. An easy way to overpass the above theoretical problems is to replace the constant vacuum energy with a DE that evolves with time. Nowadays, the physics of DE is considered one of the most fundamental and challenging problems on the interface uniting Astronomy, Cosmology and Particle Physics and indeed in the last decade there have been theoretical debates among the cosmologists regarding the nature of this exotic component.

In the original scalar field models \textsuperscript{15} and later in the quintessence context, one can ad-hoc introduce an adjust-
ing or tracker scalar field $\phi$ (different from the usual SM Higgs field), rolling down the potential energy $V(\phi)$, which could resemble the DE $^{10,11,17,20}$. This class of DE models have been widely used in the literature due to their simplicity. Notice that DE models with a canonical kinetic term have a dark energy EoS parameter $-1 \leq w_\phi < -1/3$. Models with $(w_\phi < -1)$, sometimes called phantom DE $^{21}$, are endowed with a very exotic nature, like a scalar field with negative kinetic energy. However, it was realized that the idea of a scalar field rolling down some suitable potential does not really solve the problem because $\phi$ has to be some high energy field of a Grand Unified Theory (GUT), and this leads to an unnaturally small value of its mass, which is beyond all conceivable standards in Particle Physics. As an example, utilizing the simplest form for the potential of the scalar field, $V(\phi) = m_\phi^2 \phi^2/2$, the present value of the associated vacuum energy density is $\rho_V = (V(\phi)) \sim 10^{-11}$ eV$^{-4}$, so for $\langle \phi \rangle$ of order of a typical GUT scale near the Planck mass, $M_P \sim 10^{19}$ GeV, the corresponding mass of $\phi$ is expected in the ballpark of $m_\phi \sim H_0 \sim 10^{-33}$ eV.

Notice that the presence of such a tiny mass scale in scalar field models of DE is generally expected also on the basis of structure formation arguments $^{22,24}$, namely from the fact that the DE perturbations seem to play an insignificant role in structure formation for scales well below the sound horizon. The main reason for this homogeneity of the DE is the flatness of the potential, which is necessary to produce a cosmic acceleration. Being the mass associated to the scalar field fluctuation proportional to the second derivative of the potential itself, it follows that $m_\phi$ will be very small and one expects that the magnitude of DE fluctuations induced by $\phi$ should be appreciable only on length scales of the order of the horizon. Thus, equating the spatial scale of these fluctuations to the Compton wavelength of $\phi$ (hence to the inverse of its mass) it follows once more that $m_\phi \lesssim H_0 \sim 10^{-33}$ eV.

Despite the above difficulties there is a class of viable models of quintessence usually called dilatonic that are based on supersymmetry, supergravity and string-theory and which can protect, for specific potentials, the light mass of quintessence (for a review see Ref. $^{23}$ and references therein). In particular, in string theory, gauge and gravitational couplings are connected with the vacuum expectation value of scalar field called dilaton $\phi$ $^{24}$. In this context, it has been proposed by some of us a specific model for the DE. This DE model being associated with a rolling dilaton field that is a remnant of this non-equilibrium phase described by a generic non-critical (Liouville) string theory $^{27,30}$. We call this scenario either Q-cosmology or Liouville cosmology. This pattern is based on non-critical (Liouville) strings $^{31,33}$, which offer a mathematically consistent way of incorporating time-dependent backgrounds in string theory. We note in passing that the presence of time dependent dilaton fields at late eras of the Universe, that characterizes Q-cosmology, may lead to phenomenologically interesting extensions of minimal supergravity models. The latter predict less dark-matter relic abundances than the conventional $\Lambda$CDM model, thereby allowing for more room for supersymmetry in collider (such as LHC) tests of the models $^{30,34}$.

In this article we investigate the main dynamical properties of the Q-cosmological model from the point of view of current astrophysical constraints, extending non-trivially earlier analyses $^{35,36}$. Initially, a joint statistical analysis, involving the latest observational data [SNIa $^{4}$, $H(z)$ $^{57}$] and BAO $^{38,40}$ is implemented. Secondly, we attempt to compare the matter fluctuation field of the Q-cosmology with that of the $\Lambda$CDM models by computing the growth rate of clustering. Finally, by using the Press-Schechter formalism $^{41}$ and recently derived functional forms for the dark matter halo mass function $^{12}$, we show that the evolution of the cluster-size halo abundances is a potential discriminator between the Q-cosmology and $\Lambda$CDM models. We would like to stress here that the abundance of collapsed structures, as a function of mass and redshift, can be accessed through observations $^{43}$. Indeed, the mass function of galaxy clusters has been measured based on X-ray surveys $^{44,46}$, via weak and strong lensing studies $^{47,49}$, using optical surveys, like the SDSS $^{50,51}$, as well as, through Sunayev-Zeldovich (SZ) effect $^{52}$. In the last decade many authors have found that the abundance of collapsed structures is affected by the presence of a dark energy component $^{53,65}$.

The structure of our paper is as follows. The basic elements of the Liouville cosmological model are presented in Section II where we also introduce the cosmological equations for a flat Friedmann-Lemaître-Robertson-Walker (FLRW) geometry. In Section III a joint statistical analysis based on SNIa, $H(z)$ and BAO is used to constraint the Liouville model free parameter. The issue related with the effective DE equation of state parameter and thus with the cosmic expansion is presented in Section IV. The linear growth factor of matter perturbations is discussed in Section V while in Section VI we discuss and compare the corresponding theoretical predictions regarding the evolution of the cluster abundances. Finally, the main conclusions are summarized in Section VII.

II. THEORETICAL BACKGROUND ON Q-COSMOLOGY

In non-critical Q-cosmological models the (effective, four-dimensional) Friedman equation is modified, including, apart from the standard matter and dark energy contributions denoted collectively by $\rho$, also Liouville-string off-shell corrections, $\Delta \rho$, which are not positive definite in general (without affecting, however, the overall positive-energy conditions of this non-equilibrium theory):

$$H^2(z) = \frac{8\pi G_N}{3} \rho + \Delta \rho \quad (1)$$
The detailed form of the system of dynamical equations, one of which is (1), is given by Ref. [66] in the Einstein frame [31], i.e. in the frame where the scalar curvature in the (off-shell) target space effective action assumes the canonical Einstein form to leading order in the Regge-slope \( \alpha' \) expansion, are given by

\[
3H^2 - \ddot{\varrho}_m - \varrho_\phi = \frac{e^{2\phi}}{2} \ddot{G}_\phi
\]

\[
2 \dot{H} + \ddot{\varrho}_m + \varrho_\phi + \ddot{p}_m + p_\phi = -\frac{\ddot{G}_{ii}}{a^2}
\]

\[
\ddot{\phi} + 3H \dot{\phi} + \frac{1}{4} \frac{\partial^2 \hat{V}_{all}}{\partial \phi^2} + \frac{1}{2} (\ddot{\varrho}_m - 3\ddot{p}_m) = -\frac{3}{2} \frac{\ddot{G}_{ii}}{a^2} - \frac{e^{2\phi}}{2} \ddot{G}_\phi ,
\]

with

\[
\ddot{G}_\phi = e^{-2\phi} (\ddot{\phi} - \dot{\phi}^2 + Qe^{\phi} \dot{\phi})
\]

\[
\ddot{G}_{ii} = 2a^2 \left( \ddot{\phi} + 3H \dot{\phi} + \dot{\phi}^2 + (1-q)H^2 + Qe^{\phi}(\dot{\phi} + H) \right)
\]

and \( q \) is the deceleration \( q \equiv -\ddot{a}/\dot{a}^2 \). Above, an over-dot denotes derivative with respect to the FLRW cosmic time \( t \), \( \ddot{\varrho}_m \), \( \ddot{p}_m \) denote “matter” energy and pressure densities respectively, whilst

\[
\varrho_\phi = \frac{1}{2} (2\dot{\phi}^2 + \hat{V}_{all})
\]

\[
p_\phi = \frac{1}{2} (2\dot{\phi}^2 - \hat{V}_{all})
\]

denote the dilaton energy density and pressure. In [4], the potential has the form \( \hat{V}_{all} = 2Q^2 \exp (2\phi) + V \), where \( Q = Q(t) \) is the so-called central charge deficit function of the non-critical theory, which plays the role of a “gravitational friction” coefficient. The term \( V \) represents higher-string loop corrections in the target space-stringy effective action, which are in general not known in a closed form. In our work the precise form of \( V \) will not play a role, at least for late eras of the Universe, where such quantum string corrections are sub-dominant. The variation of the central charge deficit \( Q(t) \) with the cosmic time \( t \) is provided by the following consistency equation, to leading order in the Regge-slope \( (\alpha') \) expansion:

\[
\frac{d\ddot{G}_\phi}{dt} = -6 e^{-2\phi} (H + \dot{\phi}) \frac{\ddot{G}_{ii}}{a^2} .
\]

The reader should notice that, although we have assumed a (spatially) flat Universe, the terms on the r.h.s. of (2), which manifest departure from criticality, act in a sense like curvature terms as being non-zero at certain epochs.

The continuity equation for matter, which follows by combining the set of equations (2), reads:

\[
\frac{d\ddot{\varrho}_m}{dt} + 3H (\ddot{\varrho}_m + \ddot{p}_m) + \frac{Q}{2} \frac{\partial \hat{V}_{all}}{\partial Q} = \ddot{\phi} (\ddot{\varrho}_m - 3\ddot{p}_m) = 6 (H + \dot{\phi}) \frac{\ddot{G}_{ii}}{a^2} .
\]

To proceed further one needs to make some extra assumptions. First we assume that the matter-energy density is split as

\[
\ddot{\varrho}_m = \varrho_d + \varrho_r + \varrho_\delta .
\]

The first term on the right-hand-side of (7) refers to as “dust”, \( \varrho_d \), and includes the baryonic matter and any other sort of matter, characterized by \( w = 0 \), which does not feel the effect of the non-critical terms. Following Ref. [66] we may assume that dust does not couple to the dilaton and the non-critical-stringy corrections at late eras, so that its respective density, \( \varrho_d \), obeys the standard energy conservation equation (c.f. (6)):

\[
\frac{d\varrho_d}{dt} + 3H \varrho_d \simeq 0 .
\]

The second term in (7) refers to radiation \( \varrho_r = \frac{1}{3} \) and the third term to an unknown sort of exotic matter which is characterized by an equation of state of (hereafter EoS) having a weight \( w_3 \). In our analysis for late epochs of the Universe, such as the eras of structure formation, we may assume that this sort of matter which would otherwise feel the non-critical terms in the evolution of the Universe, feels predominantly only the time-dependent dilaton \( \phi \) terms in (6), i.e. its density, \( \varrho_\delta \), obeys approximately the following energy conservation equation:

\[
\frac{d\varrho_\delta}{dt} + 3H (1 - \frac{\dot{\phi}}{3H} + \varrho_3(\ddot{\varphi} + 1)) \varrho_\delta \simeq 0 ,
\]

for late eras of the Universe, e.g. corresponding to redshifts \( z \leq 2 \), where analytic treatments of the Liouville Q-cosmology are available. In general the exotic matter equation of state \( \varrho_3(z) \) depends on the redshift, but in our analysis in this work we consider it to be a constant.

For late epochs of the Universe, an approximate scaling behavior of the dilaton field may be found by making the further assumption that its configuration is not affected much by the presence of matter. In such a case, one may use the purely gravitational solution of Ref. [28], which expresses the dilaton in the form:

\[
\phi \simeq c_1 + \phi_0 \ln(a(t)) ,
\]

in units of the present scale factor \( a_0 = 1 \), where \( c_1, \phi_0 \) are constants. In the purely gravitational theory of [28], \( \phi_0 = -1 \), but here we want to be more general, in order to account for the presence of matter, and so we shall consider the constant \( \phi_0 \) as a phenomenological parameter to be determined by fitting the data. However, we

1 A similar behavior of the dilaton is also valid in the early Universe as discussed in [34]. Such forms depend crucially on the form of the dilaton potential, which should be of exponential form \( V \sim e^{-c\phi} \), \( c \) some constant. Dilaton Q-cosmologies are indeed characterized by such potentials [33, 66].
shall assume $\phi_0 < 0$, which assumes a perturbatively weak string coupling $g_s = e^\phi$ as the cosmic time elapses, which is crucial for the validity of our analytical treatment at late epochs of the Universe. In particular, this implies that string loop corrections, although non-negligible, and in fact their inclusion may even lead to some interesting physical effects (see below) [35, 36], nevertheless they can be treated perturbatively, and thus can lead to analytic solutions at late eras.

With the above in mind, we thus observe that from (10) and (9) we obtain:

$$\frac{d\delta}{dt} + 3H \left(1 - \frac{\phi_0}{3} + w_\delta (1 + \phi_0)\right) \delta \approx 0,$$

implying the following scaling behavior of the exotic matter with the scale factor:

$$\delta \sim a^{-\delta}, \quad \delta = 3 \left(1 - \frac{\phi_0}{3} + w_\delta (1 + \phi_0)\right).$$

(12)

In particular, it has been found that $\delta \sim 4$ [36] can fit the BAO data [38]. Such a value is in the ballpark of theoretically expected values. For instance, the simplest phenomenological assumption on the pertinent EoS parameter $w_\delta = \frac{d\ln P}{d\ln a}$ of the exotic dark matter fluid, consistent with Big-Bang-nucleosynthesis constraints, is that $w_\delta \sim 0.4$ [67]. To obtain $\delta \sim 4$, while maintaining the feature $\phi_0 < 0$, one must use either values of $|\phi_0| \ll 3$, implying a weak dependence of the dilaton on the scale factor, or $\phi_0 \sim -1$ and more generally the condition

$$\frac{\dot{\phi}}{H} \sim -1,$$

in which case (10), (11) become independent of $w_\delta$.

On the other hand, the BBN constraint is also satisfied in models where the dilaton dominates the early eras of the Universe [34], in the absence of non-critical string effects, with the exotic matter behaving as dust $w_\delta = 0$ coupled to the dilaton. In this case, the scaling exponent (12) becomes: $\delta \sim 3 + |\phi_0|$. The phenomenologically likely [36] value $\delta \sim 4$ is then achieved for $|\phi_0| \sim 1$, which is in the range of the analytical solutions for late eras found in [28], and for which, as already mentioned, the energy equation (11) is largely independent of $w_\delta$.

Following the above discussion, we therefore parametrize the normalized Hubble parameter of this model, $E(z) = H(z)/H_0$, where $z$ is the redshift, as follows [35]:

$$E(z) = \left[\Omega_3 (1 + z)^3 + \Omega_\delta (1 + z)^\delta + \Omega_2 (1 + z)^2\right]^{1/2},$$

(13)

with

$$\Omega_3 + \Omega_\delta + \Omega_2 = 1.$$

(14)

It is interesting to mention that the current normalized Hubble function Eq. (13) has a form which is close to a polynomial one. Note that a quadratic polynomial dark energy has been proposed by Sahni et al. [67]. We would like to stress once again that the above formulas are valid for late eras, such as the ones pertinent to the supernova and other data ($0 \leq z \leq 2$).

In this framework, the various $\Omega_i$ contain contributions from both dark energy and matter energy densities. Specifically, $\Omega_3$ does not merely represent ordinary matter effects, but also receives contributions from the dilaton dark energy. In fact, the sign of $\Omega_3$ depends on details of the underlying theory, and it could even be negative. In a similar vein, the exotic contributions scaling as $(1 + z)^\delta$ are affected by the off-shell Liouville terms of $Q$-cosmology. It is because of the similar scaling behaviors of dark matter and dilaton dark energy that we reverted to the notation $\Omega_i, i = 2, 3, \delta$ in Refs. [35, 36]. In order to distinguish ordinary matter from dilaton dark energy effects that scale similarly with the redshift, one would have to perform also measurements of the effective dark energy EoS parameter (see Section IV).

### III. LIKELIHOOD ANALYSIS

Let us now discuss the statistical treatment of the observational data used to constrain the Liouville model presented in the previous section. To begin with, we consider the Union supernovae Ia set of Kowalski et al. [4], which contains 307 entries. The likelihood estimator is determined by a $\chi^2_{\text{SNIa}}$ statistics:

$$\chi^2_{\text{SNIa}} = \sum_{i=1}^{307} \left[\frac{\mu_{\text{th}}(z_i, \Omega_3, \Omega_\delta) - \mu_{\text{obs}}(z_i)}{\sigma_i}\right]^2,$$

(15)

where $z_i$ is the the observed redshift, $\mu$ is the distance modulus $\mu = m - M = 5 \log d_L + 25$ and $d_L$ is the luminosity distance,

$$d_L(z) = (1 + z)r(z), \quad r(z) = c \int_0^z \frac{dy}{H(y)},$$

(16)

In addition to the SNIa data, we also consider the BAO scale produced in the last scattering surface by the competition between the pressure of the coupled baryon-photon fluid and gravity. The resulting acoustic waves leave (in the course of the evolution) an overdensity signature at certain length scales of the matter distribution. Evidence of this excess was recently found in the clustering properties of SDSS galaxies [35, 40] and it provides a suitable “standard ruler” for constraining dark energy models. We would like to remind the reader that in the Liouville cosmology the ordinary matter component which appears in the normalized Hubble parameter Eq. (13) is mixed with the “exotic” contributions. Thus we cannot use the measurements of BAO derived by [35, 40]. To overcome this problem Mavromatos & Mitsou [36, 40] have proposed a different estimator which is valid...
for Liouville cosmologies. This is

\[
B \equiv \left[ \left( \int_0^{z_{\text{BAO}}} \frac{dz}{E(z)} \right)^2 \frac{z_{\text{BAO}}}{E(z_{\text{BAO}})} \right]^{1/3}
\]

where \( z_{\text{BAO}} = 0.35 \). Note that the measured value is \( B = 0.334 \pm 0.021 \) [36]. Therefore, the corresponding \( \chi^2_{\text{BAO}} \) function can be written as:

\[
\chi^2_{\text{BAO}} = \frac{(B(\Omega_3, \Omega_5) - 0.334)^2}{0.021^2}.
\]

Finally, a very interesting geometrical probe of dark energy is provided by the measures of \( H(z) \) from the differential ages of passively evolving galaxies (hereafter \( H(z) \) data). Note that the sample contains 11 entries spanning a redshift range of 0 \( \leq z < 2 \). In this case the corresponding \( \chi^2_H \) function can be written as:

\[
\chi^2_H = \sum_{i=1}^{11} \left[ \frac{H_{\text{th}}(z_i, \Omega_3, \Omega_5) - H_{\text{obs}}(z_i)}{\sigma_i} \right]^2,
\]

where \( H(z) \) is the Hubble parameter, \( H(z) = H_0 E(z) \).

In order to put tighter constraints on the corresponding parameter space of our cosmological model, the above probes are combined through a joint likelihood analysis\(^2\), given by the product of the individual likelihoods according to: \( \mathcal{L}_{\text{tot}} = \mathcal{L}_{\text{SN1a}} \times \mathcal{L}_{\text{BAO}} \times \mathcal{L}_{\text{H}}, \) which translates in the joint \( \chi^2 \) function in an addition: \( \chi^2_{\text{tot}} = \chi^2_{\text{SN1a}} + \chi^2_{\text{BAO}} + \chi^2_H \). The resulting best fit parameters for different values of \( \delta \), are presented in Table I. The current statistical results are in very good agreement with those found by [36].

TABLE I: Results of the likelihood function analysis. The 1\(^{st}\) column indicates the Liouville model. 2\(^{nd}\) column presents the values of \( \delta \) used. 3\(^{rd}\), 4\(^{th}\) and 5\(^{th}\) columns show the best fit parameters and the reduced \( \chi^2_{\text{tot}} \). In the final column one can find various line types of the models appearing in Figs. 1 and 2.

| Model | \( \delta \) | \( \Omega_3 \) | \( \Omega_5 \) | \( \chi_{\text{tot}}^2/317 \) | Symbols |
|-------|-------------|----------------|----------------|----------------|---------|
| \( Q_1 \) | 4.3 | -1.43 \pm 0.14 | 0.27 \pm 0.02 | 1.030 | solid |
| \( Q_2 \) | 4.1 | -1.64 \pm 0.16 | 0.40 \pm 0.04 | 1.028 | dashed |
| \( Q_3 \) | 3.9 | -1.93 \pm 0.19 | 0.59 \pm 0.06 | 1.027 | dotted |
| \( Q_4 \) | 3.7 | -2.45 \pm 0.25 | 0.95 \pm 0.10 | 1.025 | triangles |
| \( Q_5 \) | 3.5 | -3.29 \pm 0.33 | 1.63 \pm 0.17 | 1.024 | open circles |

\(^2\) The Hubble constant is \( H_0 = 73.8 \pm 2.4 \) km/s/Mpc [68].

\(^3\) Likelihoods are normalized to their maximum values. In the present analysis we always report 1\(\sigma\) uncertainties on the fitted parameters. Note also that the total number of data points used here is \( N_{\text{tot}} = 317 \), while the associated degrees of freedom are: \( \text{dof} = 317 \). Note that we sample \( \Omega_3 \in [-4, 1] \) and \( \Omega_5 \in [0, 1] \) in steps of 0.001.

The reader may worry that negative dust-like energy densities indicate an instability of the model and an obvious violation of the positive energy conditions, and thus its immediate exclusion. However, as discussed in [35, 36], and already mentioned in the previous section, the “dust”-like contributions, \( \Omega_3 \), do not merely represent ordinary matter effects, but also receive contributions from the dilaton dark energy. In fact, the sign of \( \Omega_3 \) depends on details of the underlying theory, and it could even be negative. For instance, as argued in [35], string loop corrections could lead to a negative \( \Omega_3 \). In addition, Kaluza-Klein graviton modes in certain brane-inspired models [69] also yield negative dust contributions. In a similar vein, the exotic contributions scaling as \( (1 + z)^d \) are affected by the off-shell Liouville terms of \( Q \)-cosmology.

IV. THE RECENT EXPANSION HISTORY

In Fig 1, we plot the Hubble parameter of the current Liouville models as a function of redshift, which for redshifts \( z \gtrsim 1.5 \) appears to be different in amplitude with respect to the corresponding \( \Lambda \text{CDM} \) model expectations (dot-dashed line).

![Fig 1: Comparison of the observed (solid circles) and theoretical evolution of the Hubble parameter, \( H(z) \), using \( H_0 = 73.8 \pm 2.4 \) km/s/Mpc [68]. The different Liouville models are represented by different symbols and line types (see Table I for definitions). For comparison, the dot-dashed line corresponds to the traditional \( \Lambda \text{CDM} \) model, while the thick line error bars correspond to 1\(\sigma\) \( H_0 \)-uncertainties. We do not plot the 1\(\sigma\) \( H_0 \)-uncertainties for the Liouville models in order to avoid confusion.

As we have already mentioned in Section I, the density related with the \( \Omega_3 \) parameter varies as \( \rho_m(z) \propto (1 + z)^3 \). Owing to the fact that the density of ordinary matter (baryons and usual cold dark matter), denoted \( \rho_m \), from now on, follows the same power-law as \( \rho_m(z) \propto (1 + z)^3 \), we are completely justified to assume that the usual matter density is one of the components of the density \( \rho_{\text{M}}(z) \). In other words the \( \Omega_m(z) = \rho_m(z)/\rho_c(z) \) density parameter (where \( \rho_c(z) = 3H^2(z)/8\pi G \) is the critical
density parameter) is included in the \( \Omega_3(z) \) parameter. On the other hand, as a result of the existence of non-trivial dilaton couplings to some dark matter species, as mentioned previously, there is dark matter with exotic scaling \( \Omega_3(1+z)^{\delta} \), with \( \delta \) given by [12]. Although this is not a dark energy contribution, nevertheless it is the dilaton couplings that modify its scaling, and therefore in this sense, the origin of this exotic scaling may be attributed to the interaction of dilaton dark energy with dark matter. However, since the \( \Omega_3 > 0 \) represents massive matter, it may cluster and lead to non-trivial contributions to structure growth in the Universe. In this sense, it is distinguishable from dark energy contributions that are non-clustering. One of our points in this work is an attempt to distinguish phenomenologically whether the current astrophysical data point out towards clustering of this exotic matter, and hence contribution to structure formation and growth, or not.

To this end, we first write the normalized Hubble parameter Eq. [13] as follows

\[
E(z) = \frac{H(z)}{H_0} = \left[ \Omega_m(1+z)^3 + \Delta H(z)^2 \right]^{1/2} \tag{20}\]

with

\[
\Delta H(z)^2 = \Omega_4(1+z)^{\delta} + (\Omega_3 - \Omega_m)(1+z)^3 + \Omega_2(1+z)^2. \tag{21}\]

Notice here that in the above formula we have been careful to isolate the matter contributions, pertaining to dust \( \Omega_4 \) (for baryons and dust dark matter \( \Omega_1 = \rho_0/\rho_c \)), from the exotic matter terms, \( \Omega_3 \) with non-trivial equation of state \( \omega_3 \), corresponding to a scaling exponent \( \delta \) [12]. It should be stressed that the last term \( \Delta H(z)^2 \) of the normalized Hubble function [20] encode the \( Q \)-cosmology corrections to the standard FLRW expression.

Since the corresponding components exhibit smooth scaling with the redshift, the absorption of these extra effects to an “effective dark energy” contribution, with a non-trivial EoS is possible. In general, it is well known that one can express the effective dark energy EoS parameter in terms of the normalized Hubble parameter [70]

\[
w_{\text{DE}}(a) = -1 - \frac{2}{3} \frac{d \ln E}{d \ln a} \tag{22}\]

where in our case

\[
\Omega_m(a) = \frac{\Omega_m a^{-3}}{E^2(a)}. \tag{23}\]

Differentiating the latter and utilizing Eq. [22] we find that

\[
\frac{d \Omega_m}{d \ln a} = 3w_{\text{DE}}(a)\Omega_m(a) [1 - \Omega_m(a)] \tag{24}\]

Notice that we will use the above quantity in Section [V].

After some simple algebra, it is also readily seen that the effective dark energy EoS parameter is given by (see [71]):

\[
w_{\text{DE}}(a) = -1 - \frac{1}{3} \frac{d \ln \Delta H^2}{d \ln a} \tag{25}\]

or

\[
w_{\text{DE}}(z) = -1 + \frac{1}{3} \frac{d \ln \Delta H^2}{d \ln(1+z)} \tag{26}\]

where \( a = (1+z)^{-1} \). From the above analysis it becomes clear that any modifications to the EoS parameter are included in the second term of Eq. [26]. A similar analysis for other DE models can be found in [71, 72].

In our case, on inserting Eq. [21] into Eq. [26] it is straightforward to obtain a simple analytical expression for the effective dark energy EoS parameter:

\[
w_{\text{DE}}(z) = -1 + \frac{1}{3} \frac{3(\Omega_3 - \Omega_m)(1+z) + \delta \Omega_3(1+z)^{\delta - 2} + 2\Omega_2}{(\Omega_3 - \Omega_m)(1+z) + \Omega_3(1+z)^{\delta - 2} + \Omega_2}. \tag{27}\]

It thus follows that in the current cosmological context, the Liouville scenario as proposed by Ellis et al. [35] can be treated by an additional effective fluid with EoS parameter defined by Eq. [24]. In order to investigate the behavior of the effective EoS parameter we have to know a priori the value of \( \Omega_m \). The matter density \( \Omega_m \) remains the most weakly constrained cosmological parameter. In principle, \( \Omega_m \) is constrained by the maximum likelihood fit to the WMAP [6] and SNIa [4] data in the context of the concordance \( \Lambda \)CDM cosmology. However, in the spirit of this work, we want to use measures which are completely independent of the dark energy component. An estimate of \( \Omega_m \) without conventional priors is not an easy task in observational cosmology. Nevertheless, various authors, using mainly large scale structure studies, have attempted to set constraints on the \( \Omega_m \) parameter.

In a rather old paper, Plionis et al. [78], using the motion of the Local Group with respect to the cosmic microwave background, found that \( \Omega_m \simeq 0.30 \). From the analysis of the power spectrum, Sanchez et al. [74] obtained a value \( \Omega_m \simeq 0.24 \). Moreover, the authors of Refs. [77, 76] analyzed the peculiar velocity field in the local Universe and obtained the values \( \Omega_m \simeq 0.30 \) and \( \simeq 0.22 \) respectively. In addition, the authors of Ref. [74], based on the cluster mass-to-light ratio, claim that \( \Omega_m \) lies in the interval 0.15 – 0.26 (see also [78] for a review). Therefore, there are strong independent indications that \( \Omega_m \) lies in the range \( 0.2 \lesssim \Omega_m \lesssim 0.3 \). In order to compare our results with those of the flat \( \Lambda \)CDM model, we shall restrict our present analysis to an indicative value of \( \Omega_m = 0.28 \).

In order to visualize the redshift dependence of the effective EoS parameter, we compare in the upper panel of Fig. [2] various flat Liouville cosmological models (see Table [1]). One can divide the evolution of the cosmic expansion history in different phases on the basis of the varying behavior of the Liouville and \( \Lambda \)CDM models. We
will investigate such variations in terms of the deceleration parameter, \( q(z) = -[1 - d \ln H / d \ln (1 + z)] \), which is plotted in the lower panel of Fig. 2. We can divide the cosmic expansion history in the following phases:

- At early enough times \( z \sim 2 \) the deceleration parameters of both models are positive with \( q_0 < q_\Lambda \), which means that the \( \Lambda \)CDM model is more decelerating than the Liouville model.

- For \( 1.6 < z < 1.9 \) the deceleration parameters are both positive with \( q_0 > q_\Lambda \), which means that the cosmic expansion in the Liouville model is more rapidly “decelerating” than in the \( \Lambda \)CDM case. Note that the effective EoS parameter of the \( Q \) model tends to its maximum value, \( w_\text{DE}(z) \sim 1.4 \), while we always have \( w_\text{DE} = -1 \) for the \( \Lambda \)CDM model (dot-dashed line);

- Between \( 1.1 < z < 1.6 \) the deceleration parameters remain positive (with \( q_0 < q_\Lambda \)) but \( q_0 \) decreases rapidly.

- For \( 0.7 < z < 1.1 \) the traditional \( \Lambda \)CDM model remains in the decelerated regime (\( q_\Lambda > 0 \)) but the Liouville model is starting to accelerate (\( q_0 < 0 \), \( w_\text{DE} < -1/3 \)). At \( z \sim 0.9 \) the corresponding effective EoS parameter cross, for the first time, the phantom divide (\( w_\text{DE} = -1 \)) and it stays there for some time (\( 0.2 < z < 0.9 \)).

- Prior to the present epoch the effective EoS parameter crosses the phantom divide for the second time (\( z \sim 0.2 \)) and then it remains close to \( w_\text{DE} \approx -0.90 \). The deceleration parameters are both negative and since \( q_0 > q_\Lambda \), the \( \Lambda \)CDM model provides a stronger acceleration than in the Liouville model. At the present time we find \( q_{0,0} \approx -0.33 \) and \( q_{\Lambda,0} \approx -0.60 \)

V. THE GROWTH FACTOR AND THE RATE OF CLUSTERING

In this section, we discuss the basic equation which governs the behavior of the matter perturbations on subhorizon scales and within the framework of any dark energy model, including those of modified gravity (“geometrical dark energy”).

The basic assumption underlying the approach is that whatever we call “dark energy” contribution in our effective approach, pertains to a substance that is non clustering to participate significantly in the growth of cosmic structures. In our Liouville cosmology, this issue is subtle. As we have discussed above, we do have two kinds of matter in the model, with two different equations of state and scaling, an ordinary dust, and an exotic dark matter component, with non trivial scaling exponent \( \delta \) \((\text{III})\), as a result of its coupling to the dilaton. The phenomenologically likely value \( \delta \sim 4 \) makes the behavior of exotic dark matter resembling (to a good approximation) that of relativistic matter (radiation), which does not cluster. We shall come back to this point later one. For the moment let us restrict ourselves to the ordinary matter as the dominant kind that contributes to structure formation via its clustering properties.

For these cases, a full analytical description can be introduced by considering an extended Poisson equation together with the Euler and continuity equations. Consequently, we consider here the evolution equation of the matter fluctuations for models where the DE fluid has a vanishing anisotropic stress and it is not coupled to ordinary matter (noninteracting DE see \(72, 79, 84 \)). It is well known that for small scales (smaller than the horizon) the dark energy component (or “geometrical” dark energy) is expected to be smooth and thus it is fair to consider perturbations only on the usual matter component of the cosmic fluid \(85\). This assumption leads to the traditional equation for matter perturbations (see Appendix \( A \)):

\[
\ddot{\delta}_m + 2H \dot{\delta}_m = 4\pi G \rho_m \delta_m, \tag{28}
\]

where \( \rho_m \) is the matter density which clusters in order to form cosmic structures.

We would like to emphasize here that Eq. (28) can be used also in the case of a dilaton field, as it has been
shown by Boisseau et al. \cite{86} In other words, Eq. (28) is valid also in the Liouville cosmology, as far as ordinary dust matter (including potential dark matter components scaling like dust) is concerned.

Within this latter framework, we assume that for small scales (smaller than the horizon) the effective dark energy component $\Delta H(z)$ appeared in the modified Friedmann equation \cite{20} is smooth (homogeneous) which implies that Eq. (28) is valid also in the Liouville model. If we change the variables from $t$ to $\ln a$ ($\frac{dt}{da} = \frac{4}{3} H(a) a$), then the time evolution of the mass density contrast (see Eq. (28)) takes the following form \cite{87}

$$(\ln \delta_m)'' + (\ln \delta_m)' X(a) = \frac{3}{2} \Omega_m(a),$$

where

$$X(a) = \frac{1}{2} - \frac{3}{2} w_{DE}(a) [1 - \Omega_m(a)].$$

The prime denotes derivatives with respect to $\ln a$. Now, for any type of dark energy an efficient parametrization of the matter perturbations is based on the growth rate of clustering \cite{88}

$$f(a) = \frac{d \ln \delta_m}{d \ln a} = \gamma_m(a)$$

$\gamma$ is the so called growth index \cite{71, 79, 82, 87, 89} which plays a key role in cosmological studies, especially in light of recent large redshift surveys, such as the WiggleZ \cite{90, 91}. Indeed, it has been proposed that measurement of the growth index can provide an efficient way to discriminate between modified gravity models and DE models which adhere to general relativity. As an example, it was theoretically shown that for DE models within the general relativity framework, the growth index $\gamma$ is well fitted by $\gamma_{GR} \approx 6/11$ \cite{82, 59}. Notice, that in the case of the braneworld model of Ref. 95 we have $\gamma \approx 11/16$ (see also \cite{82}), while for the $f(R)$ gravity models we have $\gamma(z) \approx 0.41$ at $z = 0$ \cite{84}.

Now, inserting Eq. (31) into Eq. (29) and using simultaneously Eq. (24) we obtain (see also \cite{87})

$$3w_{DE}(a) \Omega_m(a) [1 - \Omega_m(a)] \frac{d f}{d \Omega_m} + f'^2 + f X(a) = \frac{3}{2} \Omega_m(a)$$

Of course the above formula boils down to 6/11 for the usual $\Lambda$CDM ($w_{DE}(z) = -1$) model as it should.\footnote{\textsuperscript{5} We should point out at this stage that in order to compare the observed growth history of the Universe with predictions coming from modified gravity models, which however is not our case, one cannot use the observed $f_{Lm}(z)$ but rather a combination of the growth rate of structure and the rms fluctuations of the linear density field on scales of $8h^{-1}$Mpc, namely $f(z)\sigma_8(z)$. This is a model independent quantity (see e.g. \cite{91} and references therein).

\textsuperscript{4} The authors of \cite{86} have worked in the so-called Jordan frame, in which the dilaton couples to the Einstein scalar curvature term in the (four space-time dimensional) action through a function \cite{28}

$$F(\phi) = \frac{1}{2} R - \frac{1}{2} g^{\mu\nu} \partial_{\mu} \phi \partial_{\nu} \phi - V(\phi) + L_{\text{dust matter}}(g_{\mu\nu}).$$

In this formalism there is an effective gravitational “constant”, $G_{\text{eff}}(\phi)$, which is a function of the dilaton that replaces $G$ in \cite{28}. Notice that the matter action does not couple to the dilaton in the Jordan frame. In our Liouville string cosmology case we have an additional component to the matter action, $L_{\text{exotic matter}}(g_{\mu\nu}, \phi)$, involving the exotic dark matter, with equation of state $w_f$, and its interactions with the ordinary baryonic or dark matter with dust scaling. This depends on the dilaton in the Jordan frame. In the Liouville Cosmology we work in the Einstein frame, as already mentioned, by having redefined appropriately the gravitational field, in such a way that, in terms of the new metric field, there is a canonically normalized Einstein term in the effective action. Such a redefinition leaves the perturbative scattering amplitudes of low-energy string theory invariant, and hence is an allowed transformation in the string framework that does not affect the physical predictions. Under this redefinition, the matter action involves coupling of the dilaton with the dust-like matter fields, as a consequence of the redefined gravitation. Nevertheless, we still assume for our purposes that such a coupling is very weak, and the only dominant couplings of the dilaton to matter fields in the Einstein frame are the ones pertaining to the exotic dark matter components. As we shall discuss below, such assumptions can be put directly to experimental tests by studying galactic growth data.}
In Table III we quote the observational values of the growth rate of clustering, with the corresponding error bars. This is an enriched version of the dataset used in 89, which includes in addition data from the WiggleZ 90. The observed growth rate of clustering is given by $f_{\text{obs}} = \beta b$, where $\beta(z)$ is the redshift space distortion parameter and $b(z)$ is the linear bias. Observationally, one can estimate the $\beta(z)$ parameter by using the anisotropy of the correlation function. The linear bias factor can be defined as the ratio of the variances of the tracer (galaxies, QSOs, etc) and underlying mass density fields, smoothed out at the scale $8h^{-1}$ Mpc, at which the variance is of order unity: $b(z) = \sigma_{8,\text{tr}}(z)/\sigma_b(z)$, where $\sigma_{8,\text{tr}}(z)$ is measured directly from the sample. As discussed in 89, the weak point of the $f_{\text{obs}}(z)$ data is the fact that the $\sigma_b(z)$ is defined at each redshift using a particular reference (fiducial) ΛCDM model (see third column in Table II). Moreover, the growth measurements are correlated with the shape of the power spectrum, which makes the growth rate sample rather heterogeneous 91, 92. In our analysis, we ignore the effects of such a heterogeneity. Such simplifying assumptions in treating the growth rate data have been used extensively in the literature in order to put constraints on the growth index $\gamma$, especially in the context of the braneworld cosmological model 93. We would like to stress that in the present work, due to the above caveats, we do not use the $f_{\text{obs}}(z)$ data to constrain the cosmological parameters or the growth index. Instead, by using the constraints found from the cosmic expansion data (see section III), we shall only compare the evolution of the predicted Liouville growth rate of structure with the data (for a similar analysis see 94).

In Fig. 3 we display the predicted growth rate Eq. (31) together with the observed $f_{\text{obs}}(z)$ 97. We compare the growth rate of clustering between data and models via a $\chi^2$ statistical test. For the model predictions we use the best fitted values for the parameters ($\Omega_\Lambda$ and $\Omega_m$) obtained in Section III for each Liouville model. We then compute the corresponding consistency between models and data ($\chi^2_{\text{min}}/11$) and place these results in Table III. For the Liouville models we find $\chi^2_{\text{min}}/11 \simeq 1.19$ while in the case of the concordance ΛCDM cosmology we find $\chi^2_{\text{min}}/11 \simeq 0.60$. Note that in the last column of Table III we list the corresponding results by excluding from the statistical analysis the observed growth rate of clustering at $z = 3$ 98. If we consider $\Omega_m = 0.30$, we then find either $\chi^2_{\text{min}}/11 \simeq 1.47$ or $\chi^2_{\text{min}}(z < 3)/10 \simeq 0.70$.

**TABLE II:** Data of the growth rate of clustering. The correspondence of the columns is as follows: redshift, observed growth rate, cosmological parameters use by different authors and references.

| $z$ | $f_{\text{obs},\text{Ref}}$ | $(\Omega_m,\text{Ref},\sigma_b,\text{Ref})$ | Refs. |
|-----|-----------------|---------------------------------|------|
| 0.15 | 0.49 ± 0.14     | (0.30, 0.90)                   | 99-101 |
| 0.22 | 0.60 ± 0.10     | (0.27, 0.80)                   | 90   |
| 0.35 | 0.70 ± 0.18     | (0.24, 0.76)                   | 102  |
| 0.41 | 0.70 ± 0.07     | (0.27, 0.80)                   | 90   |
| 0.55 | 0.75 ± 0.18     | (0.30, 1.00)                   | 103  |
| 0.60 | 0.73 ± 0.07     | (0.27, 0.80)                   | 90   |
| 0.77 | 0.91 ± 0.36     | (0.27, 0.78)                   | 90   |
| 0.78 | 0.70 ± 0.08     | (0.27, 0.80)                   | 90   |
| 1.40 | 0.90 ± 0.24     | (0.25, 0.84)                   | 104  |
| 2.42 | 0.74 ± 0.24     | (0.26, 0.93)                   | 105  |
| 3.00 | 1.46 ± 0.29     | (0.30, 0.85)                   | 98   |

**TABLE III:** Statistical quantification of the comparison between the observed growth rate of clustering (see Table II) and the theoretical model expectations. The last column corresponds to comparison excluding the observed growth rate of clustering at $z = 3$ 98.

| Model | $\chi^2_{\text{min}}/11$ | $\chi^2_{\text{min}}(z < 3)/10$ |
|-------|-----------------|---------------------------------|
| Q-Data | 1.19            | 0.90                            |
| Λ-Data | 0.60            | 0.45                            |

Finally, let us now examine the case in which the density $\rho_\delta(z) \propto (1 + z)^3$ participates in the clustering. The situation is subtle. As we have discussed above, the exotic matter obeys a modified energy equation, as a result of its direct coupling to the dilaton sources in the conservation Eqs. (10) and (11). Thus, in addition to the existence of pressure in the exotic dark matter fluid, due to a possibly non-trivial equation of state, $w_\delta$, one has the effects of the dilaton coupling that also contribute to the growth equation. For $\phi_0 \sim -1$ in (10), or more generally $\phi \sim -H$, the modified conservation equation (11) becomes independent of the equation of state $w_\delta$:

$$\dot{\rho}_\delta + 3(1 + \nu)H \rho_\delta \simeq 0,$$  (36)
where $\nu = 1/3$. This energy equation resembles that of a radiation fluid, with effective scaling law for the density $\rho_8 \sim a^{-4}$. However, the reader must bear in mind that the energy equation (30) stems from the time-dependent dilaton-sources modified energy equation (9), which for the case at hand, $\dot{\phi} \sim -H$, is independent of the true equation of state $w_8$. Within the standard Cosmological framework, the growth equation for radiation is modified, as compared to that for matter (28), by terms larger by a factor of about $(1 + \nu)(1 + 3\nu) = 8/3$ (10).

$$\ddot{\delta} + 2H\dot{\delta} \simeq 4\pi G(1 + \nu)(1 + 3\nu)\rho_8\delta = 4\pi G\delta. \quad (37)$$

In this case the growing mode scales as $\delta_\nu \sim a^{1+3\nu}$ at large redshifts which implies that the growth rate takes a large value $f_\nu \sim 1 + 3\nu = 2$. The latter value seems to be ruled out by the observed growth rate of clustering.

**VI. COMPARISON WITH CLUSTER HALO ABUNDANCES**

Since the Liouville cosmology appears not to be ruled out by the growth rate data, it is important to define observational criteria that will enable us to distinguish between it and the concordance ΛCDM cosmology. An obvious choice, that has been extensively used so far, is to extract the theoretical predictions of the models for the cluster-size halo redshift distributions and to confront them with the data. This will allow distinguishing the Q-cosmology from the ΛCDM model. Recently, the halo abundances predicted by a large variety of DE models have been compared with those corresponding to the ΛCDM model [64]. As a result, it is suggested that many DE models (including some of modified gravity) are clearly distinguishable from the ΛCDM cosmology.

We use the Press and Schechter [41] formalism, which determines the fraction of matter that has formed bounded structures as a function of redshift. Mathematical details of such a treatment can be found also in [64]; here we only present the basic ideas. The number density of halos, $n(M, z)$, with masses within the range $(M, M + 6M)$ is given by:

$$n(M, z)dM = \tilde{\rho} \frac{d\sigma^{-1}}{dM} f(\sigma) dM, \quad (38)$$

where $\tilde{\rho}$ is the mean mass density. In the original Press-Schechter (PSc) formalism, $f(\sigma) = f_{PSc}(\sigma) = \sqrt{2/\pi}\delta_c/\sigma \exp(-\delta_c^2/2\sigma^2)$, $\delta_c$ is the linearly extrapolated density threshold above which structures collapse [107], while $\sigma^2(M, z)$ is the mass variance of the smoothed linear density field, extrapolated to redshift $z$ at which the halos are identified. It depends on the power-spectrum of density perturbations in Fourier space, $P(k)$, for which we use here the CDM form according to [108], and the values of the baryon density parameter, the spectral slope and Hubble constant according to the recent WMAP7 results [6]. Although the original Press-Schechter mass-function, $f_{PSc}$, was shown to provide a good first approximation to that provided by numerical simulations, it was later found to over-predict/under-predict the number of low/high mass halos at the present epoch [106, 111]. More recently, a large number of works have provided better fitting functions of $f(\sigma)$, some of them based on a phenomenological approach. In the present treatment, we adopt the one proposed by Reed et al. [52].

We remind the reader that it is customary to parameterize the mass variance in terms of $\sigma_8$, the rms mass fluctuations on scales of $8h^{-1}$ Mpc at redshift $z = 0$. In order to compare the mass function predictions of the different cosmological models, it is imperative to use for each model the corresponding value of $\sigma_8$ and $\delta_c$. It is well known that for the usual ΛCDM cosmology $\delta_c \simeq 1.675$, while Weinberg & Kamionkowski [53] provide an accurate fitting formula to estimate $\delta_c$ for any DE model with a constant equation of state parameter (see their Eq.18). Although these are not satisfied by our models, one can show [61, 64] that the $\delta_c$ values for a large family of dark energy models with a time-varying EoS parameter can be well approximated using the previously discussed fitting formula, as long as the EoS parameter remains constant near the present epoch. Since for the current Liouville cosmological model ($Q_2$ with $\Omega_m = 0.28$) the effective dark energy EoS parameter remains close to $w_{DE} \simeq -0.90$, prior to the present time, implies that we can use the approximate Weinberg & Kamionkowski [53] fitting formula. Doing so we find $\delta_c \simeq 1.686$. As a further consistency check we obtain the $\delta_c$ value using the same methodology with that of Pace et al. [61]; see their Eq. (18)). We find $\delta_c \simeq 1.676$, which is in relatively good agreement with that value found by the fitting formula of [53]. Note that for $\Omega_m = 0.3$ we obtain $\delta_c \simeq 1.674$. Below we utilize those $\delta_c$ values which are based on the notation of Pace et al. [61].

Now, in order to estimate the correct normalization of the model’s $\sigma_8$ power spectrum, we use the full expression presented in Ref. [64] which scales the observationally determined $\sigma_8, \Lambda$ value to that of any cosmological model. The corresponding value for the Liouville model is $\sigma_8, Q_2 = 0.794$ and it is based on $\sigma_8, \Lambda = 0.811$ (as indicated also in Table IV), based on the WMAP7 results [6], but also consistent with an average over a variety of recent measurements (see also the corresponding discussion in [64]). For the same model but with $\Omega_m = 0.3$ we obtain $\sigma_8, Q_2 = 0.847$.

Given the halo mass function from Eq. (38) we can now derive an observable quantity which is the redshift distribution of clusters, $N(z)$, within some determined mass range, say $M_1 \leq M / h^{-1} M_\odot \leq M_2 = 10^{16}$. This can be estimated by integrating over mass the expected differential halo mass function, $n(M, z)$:

$$N(z) = \frac{dV}{dz} \int_{M_1}^{M_2} n(M, z)dM, \quad (39)$$
Below we shall provide predictions for the Liouville cosmology only for the Q2 model (see Table I). For the other Liouville models we find that our results remain practically the same (due to the small differences in the corresponding Hubble flows). In Fig. 4 (upper panels) we present the expected redshift distributions above a limiting halo mass, which is \( M_j = M_{\text{lim}} = \max[10^{13}h^{-1}M_\odot, M_f] \), with \( M_f \) corresponding to the mass related to the flux-limit at the different redshifts, estimated by solving Eq. (41) and Eq. (42) for \( M \).

In the lower panels we present the fractional difference between the Liouville model and \( \Lambda \)CDM. The error-bars shown

where \( dV/dz \) is the comoving volume element

\[
dV{dz} = \Omega_s r^2(z) \frac{dr}{dz} \quad (40)
\]

and \( \Omega_s \) is the solid angle. In order to derive observationally relevant cluster redshift distributions and therefore test the possibility of discriminating between the Liouville and the \( \Lambda \)CDM cosmological models, we will use the expectations of two realistic future cluster surveys, extensively used in recent literature:

(a) the eROSITA satellite X-ray survey, with a flux limit of \( f_{\text{lim}} = 3.3 \times 10^{-14} \text{ ergs s}^{-1} \text{ cm}^{-2} \), at the energy band 0.5–5 keV and covering \( \Omega_s \sim 20000 \text{ deg}^2 \) of the sky;

(b) the South Pole Telescope SZ survey, with a limiting flux density at \( \nu_0 = 150 \) GHz of \( f_{\nu_0, \text{lim}} = 5 \text{ mJy} \) and a sky coverage of \( \Omega_s \sim 4000 \text{ deg}^2 \).

To realize the predictions of the first survey we use the relation between halo mass and bolometric X-ray luminosity, as a function of redshift, given in Ref. [111]:

\[
L(M, z) = 3.087 \times 10^{44} \left[ \frac{ME(z)}{10^{15}h^{-1}M_\odot} \right]^{1.554} h^{-2} \text{ ergs}^{-1}. \quad (41)
\]

The limiting halo mass that can be observed at redshift \( z \) is then found by inserting in the above equation the limiting luminosity, given by \( L = 4\pi d_A^2 f_{\nu_0, \text{lim}} c_0 \), with \( d_A \) the luminosity distance corresponding to the redshift \( z \) and \( c_0 \) the band correction, necessary to convert the bolometric luminosity of Eq. (111) to the 0.5–5 keV band of eROSITA. We estimate this correction by assuming a Raymond-Smith (1977) plasma model with a metallicity of 0.4\( Z_\odot \), a typical cluster temperature of \( \sim 4 \) keV and a Galactic absorption column density of \( n_H = 10^{21} \text{ cm}^{-2} \).

The predictions of the second survey can be realized using again the relation between limiting flux and halo mass obtained in Ref. [111]:

\[
f_{\nu_0, \text{lim}} = \frac{2.592 \times 10^8 \text{ mJy}}{d_A^2(z)} \left( \frac{M}{10^{15}h^{-1}M_\odot} \right)^{1.876} E^{2/3}(z), \quad (42)
\]

where \( d_A(z) \equiv d_L/(1+z)^2 \) is the angular diameter distance out to redshift \( z \).

Below we shall provide predictions for the Liouville cosmology only for the Q2 model (see Table I). For the other Liouville models we find that our results remain practically the same (due to the small differences in the corresponding Hubble flows). In Fig. 4 (upper panels) we present the expected redshift distributions above a limiting halo mass, which is \( M_j = M_{\text{lim}} = \max[10^{13}h^{-1}M_\odot, M_f] \), with \( M_f \) corresponding to the mass related to the flux-limit at the different redshifts, estimated by solving Eq. (41) and Eq. (42) for \( M \). In the lower panels we present the fractional difference between the Liouville model and \( \Lambda \)CDM. The error-bars shown

| Model       | \( \Omega_m \) | \( \sigma_8 \) | \( \delta_c \) | \( \delta V/\delta N_{\Lambda}^{\text{eROSITA}}(z < 0.3) \) | \( \delta V/\delta N_{\Lambda}^{\text{eROSITA}}(0.6 \leq z < 0.9) \) | \( \delta V/\delta N_{\Lambda}^{\text{SPT}}(z < 0.3) \) | \( \delta V/\delta N_{\Lambda}^{\text{SPT}}(0.6 \leq z < 0.9) \) | \( \delta V/\delta N_{\Lambda}^{\text{SPT}}(1.2 \leq z < 2) \) |
|-------------|----------------|----------------|---------------|---------------------------------|---------------------------------|---------------------------------|---------------------------------|---------------------------------|
| \( \Lambda \)CDM | 0.28           | 0.811          | 1.675         | 0.00                            | 0.00                            | 0.00                            | 0.00                            | 0.00                            |
| Liouville Q2 | 0.28           | 0.794          | 1.676         | -0.05                           | -0.27 ± 0.01                    | -0.06                           | -0.15                           | -0.37                           |
| \( \Lambda \)CDM | 0.30           | 0.845          | 1.675         | 0.00                            | 0.00                            | 0.00                            | 0.00                            | 0.00                            |
| Liouville Q2 | 0.30           | 0.847          | 1.674         | 0.00                            | -0.16 ± 0.01                    | 0.00                            | -0.02                           | -0.26                           |

TABLE IV: Numerical results: The 1st column indicates the cosmological model. The next three columns list the corresponding \( \Omega_m, \sigma_8 \) and \( \delta_c \) values, respectively. The remaining columns present the fractional relative difference of the abundance of halos between the Liouville and the \( \Lambda \)CDM cosmology for two future cluster surveys discussed in the text and in various redshift intervals. Error bars are 2σ Poisson uncertainties and are shown only if they are larger than \( 10^{-2} \).
correspond to 2σ Poisson uncertainties, which however do not include cosmic variance and possible observational systematic uncertainties, that would further increase the relevant variance.

The results (see also Table IV) indicate that the redshift variation of the differences between the $Q$ cosmology and $\Lambda$CDM model is only slightly affected by variations in the value of $\Omega_m$. For the best-fit case of $\Omega_m = 0.28$ we find that significant model differences should be expected for $z \gtrsim 0.6$, with the Louville model abundance predictions being always less than those of the corresponding $\Lambda$CDM model. Therefore, we have verified that there are observational signatures that can be used to differentiate the Liouville model from the $\Lambda$CDM and possibly from a large class of DE models (see [64]). In Table IV one may see a more compact presentation of our results including the relative fractional difference between the Liouville model and the $\Lambda$CDM model, in characteristic redshift bins and for both future surveys.

VII. CONCLUSIONS

In this paper, we have studied the overall dynamics of the Liouville cosmological model in which the dark energy component is associated with the dilaton. In this framework, we first performed a joint likelihood analysis in order to put tight constraints on the main cosmological parameters by using the current observational data [SNIa, BAOs and $H(z)$]. We found that the above models can accommodate a late-time accelerated expansion.

Secondly, we performed an additional detailed statistical analysis based on the observed growth rate of clustering and found that the predicted growth rate of various Liouville cosmological models match well the observed growth rate.

The redshift-dependence of the halo abundances, predicted by the Liouville model, is significantly different from that of the flat $\Lambda$CDM cosmology, at relatively high redshifts ($z \gtrsim 0.6$). Future cluster of galaxy surveys can therefore be used to discriminate the Liouville model from other contender DE models.

Appendix A: Matter density perturbations in dark energy cosmologies

As discussed in the text, the Liouville cosmology, explored in this paper, is close to GR in the matter dominated era (see equation (1) and [66]). Hence, in this appendix we would like to remind the reader, for completeness, of some basic elements of the equations that govern the evolution of the mass density contrast, modelled as an ideal fluid in the framework of non-interacting DE cosmologies that we employ in this work. Also we assume here that for small scales (much smaller than the horizon) the (effective) dark energy component is expected to be smooth and thus we consider perturbations only on the matter component of the cosmic fluid.

In what follows we will adopt a non-relativistic description, based on a continuity equation, together with the Euler and Poisson equations. These equations are:

$$\left(\frac{\partial \rho}{\partial t} \right)_r + \nabla_r \cdot (\rho \mathbf{u}) = 0 \tag{A1}$$

$$\left(\frac{\partial \mathbf{u}}{\partial t} \right)_r + (\mathbf{u} \cdot \nabla_r) \mathbf{u} = -\nabla \Phi, \tag{A2}$$

and

$$\nabla_r^2 \Phi = 4\pi G \rho + 4\pi G \rho_{DE} (3w_{DE} + 1), \tag{A3}$$

where $(r, t)$ are the proper coordinates, $\mathbf{u}$ is the velocity of a fluid element of volume, $\rho$ is the mass density, $\rho_{DE}$ is the DE density, $w_{DE}$ is the EoS parameter (given in our case by Eq. (27)) and $\Phi$ is the gravitational potential. Note that we use here $P_m = 0$ and $P_{DE} = w_{DE} \rho_{DE}$.

Upon changing variables from proper $(r, t)$ to comoving $(x, t)$ ones, the fluid velocity becomes

$$\mathbf{u} = \dot{a} \mathbf{x} + a \dot{\mathbf{x}} = \dot{a} \mathbf{v} + \mathbf{v}(x, t), \tag{A4}$$

while the corresponding differential operators take the following form:

$$\nabla_x \equiv \nabla = a \nabla_r, \tag{A5}$$

and

$$\left(\frac{\partial}{\partial t} \right)_x \equiv \frac{\partial}{\partial t} = \left(\frac{\partial}{\partial t} \right)_r + H \mathbf{x} \cdot \nabla, \tag{A6}$$

where $\mathbf{x} = r/a$ and $\mathbf{v}(x, t)$ is the peculiar velocity with respect to the general expansion. Note that the mass density is written as

$$\rho = \rho_m(t) [1 + \delta_m(x, t)]. \tag{A7}$$
In this context, using the standard evolution equation for the energy density of ordinary dust,
\[ \dot{\rho}_m + 3H\rho_m = 0 \]
as well as Eqs. (A5), (A6) and neglecting second-order terms \((\delta_m \ll 1 \text{ and } v \ll u)\) we rewrite Eqs. (A1), (A2) and (A3) as:
\[ \ddot{a}x + \frac{\partial v}{\partial t} + Hv = -\frac{\nabla \Phi}{a}, \quad (A8) \]
\[ \nabla \cdot v = -a \frac{\partial \delta_m}{\partial t}, \quad (A9) \]
\[ \frac{1}{a^2} \nabla^2 \Phi = 4\pi G \rho_m(1 + \delta_m) + 4\pi G(3w_{DE} + 1)\rho_{DE}. \quad (A10) \]

Following the notation of [88], we can write the gravitational potential as follows
\[ \Phi = \phi(x, t) + \frac{2}{3} \pi G \rho_m a^2 x^2 + \frac{2}{3} \pi G(3w_{DE} + 1)\rho_{DE} a^2 x^2. \quad (A11) \]

Thus, utilizing the Friedmann equation and Eqs. (A11), we arrive, after some algebra, at
\[ \frac{\partial v}{\partial t} + Hv = -\frac{\nabla \phi}{a}, \quad (A12) \]
and
\[ \nabla^2 \phi = 4\pi G a^2 \rho_m \delta_m. \quad (A13) \]

Finally, by taking the divergence of Eq. (A12) and using Eqs. (A9) and (A13), we obtain the time evolution equation for the matter fluctuation field
\[ \ddot{\delta}_m + 2H \dot{\delta}_m - 4\pi G \rho_m \delta_m = 0. \quad (A14) \]

In this context, \(\delta_m(a) \propto D(a)\), where \(D(a)\) is the linear growing mode (usually scaled to unity at the present time). Note that for those cosmological models which adhere to general relativity (GR), the quantity \(G\) reduces to the usual Newton’s gravitational constant \(G_N\), while in the case of modified gravity models (see [79, 82–84]), we have \(G = G_{\text{eff}} = Y(a)G_N\) (with \(Y(a) \neq 1\)).

A well known approximate solution to Eq. (A1) is found by [82], where a growth index \(\gamma\) was used to parameterize the linear growing mode for any type of DE with a time varying equation of state. Specifically, the approximated growth factor was defined through
\[ D(a) = \exp \left[ \int_1^a \Omega_m(u) \frac{du}{u} \right], \quad (A15) \]
where now we encapsulate any modification to the \(G\) in the term \(\Omega_m(a) = \frac{\dot{a}^2}{3H^2} = \frac{\dot{a}^2}{8\pi G \rho_m a^2}\). This completes our discussion on the growth of perturbations due to ordinary matter components of the Liouville cosmology explored in this work.
