Director configuration of planar solitons in nematic liquid crystals

Henryk Arodź and Joachim Stelzer

Instytut Fizyki, Uniwersytet Jagielloński, Reymonta 4, 30-059 Kraków, Poland

Abstract

The director configuration of disclination lines in nematic liquid crystals in the presence of an external magnetic field is evaluated. Our method is a combination of a polynomial expansion for the director and of further analytical approximations which are tested against a numerical shooting method. The results are particularly simple when the elastic constants are equal, but we discuss the general case of elastic anisotropy. The director field is continuous everywhere apart from a straight line segment whose length depends on the value of the magnetic field. This indicates the possibility of an elongated defect core for disclination lines in nematics due to an external magnetic field.

PACS:
I. INTRODUCTION

Nematic liquid crystals are systems which are positionally disordered, but reveal a long-range orientational order [1]. This property is described on a mesoscopic level by a unit vector field \( n(r) \), which is called director. Due to the absence of permanent dipolar moments in nematics the director just indicates the orientation, but its has neither head nor tail. This particular feature yields very interesting defect structures in nematic liquid crystals. For instance, the director field shows line defects in three dimensions (or, equivalently, point defects in two dimensions), called disclinations, which have been studied and classified by topological methods [2–4]. Unlike in spin systems, disclinations of topological charge \( \pm \frac{1}{2} \) are possible and stable in nematics. When an external magnetic field is applied perpendicular to such a disclination line, the resulting director configuration becomes even more interesting – it can be regarded as a domain wall filling a half-plane which terminates in the disclination line. Such walls with edges, known as planar solitons [5], have been discussed for superfluid Helium-3 by Mineyev and Volovik [6]. Whereas the qualitative behaviour of these soliton-like objects is well-established, a quantitative understanding of their structure can be obtained only from a thorough analysis of the underlying field theory. Its is the aim of our paper to perform such calculations. Our approach is based on a polynomial expansion of the director field. This method has been used previously both in relativistic field theories [8,9] and for the evaluation of domain wall dynamics in nematics [10]. It yields approximate analytical solutions for the director orientation.

The paper is organized as follows. In Section II the director field equation for the planar solitons is derived. Section III develops a method for obtaining an approximate solution for the tilt angle of the director. Our technique is a combination of the polynomial expansion [8,10] with further approximations which are tested by means of a numerical shooting method [11]. The discussion is performed within the framework of the Oseen-Zöcher-Frank elasticity [12–14]. In Section IV we estimate the energy of the defect core of the planar solitons, and we minimize the total energy of the solitons in order to determine the length of the core. Section V contains concluding remarks.

II. DIRECTOR FIELD EQUATION AND BOUNDARY CONDITIONS FOR PLANAR SOLITONS

A. Free energy and field equation

The geometry for planar solitons in nematic liquid crystals is drawn schematically in Figs. 1 (positive soliton) and 2 (negative soliton). The director field is essentially planar, perpendicular to a disclination line of strength \( \pm \frac{1}{2} \) along the \( z \) direction of a Cartesian coordinate frame. Because the structure is independent on \( z \), we restrict ourselves to the \( x-y \) plane \((z = 0)\). Now we impose a magnetic field in the plane of the director along the \( x \) axis. Due to the magnetic anisotropy of the nematic the director tends to align along the magnetic field. However, the topological charge of the disclination has to be conserved. The resulting structure is a planar domain wall of Néel type [15,16,17] which ends in the disclination line [18,13]. Locally, close to the disclination, the director field preserves the defect structure. However, in a plane at a finite distance from the disclination line, which is given
by the half width $y_0$ of the planar Néel wall (Figs. 1 and 2), the director field is aligned parallel to the external magnetic field $\mathbf{H}$.

Due to the translational symmetry along the $z$ axis it is sufficient to perform the calculations in two dimensions only. The director orientation is then completely determined by the tilt angle field $\Phi(x, y)$, which is measured with respect to the direction of the magnetic field $\mathbf{H}$ ($x$ axis),

$$n = \cos \Phi(x, y) \hat{x} + \sin \Phi(x, y) \hat{y}, \quad H = H_0 \hat{x}. \quad (1)$$

We look for static director configurations, hence $\Phi$ does not depend on time.

The static director orientation inside the soliton corresponds to a configuration minimizing the total free energy $F$ (per unit length in the $z$ direction) which contains both the energy of the nematic phase $F_{\text{nem}}$ and the core energy of the disclination $F_{\text{core}}$. (Within the defect core local phase transitions may occur.) The nematic energy $F_{\text{nem}}$ is the area integral of a free energy density $F_{\text{nem}}$. This free energy density, in turn, consists of elastic contributions (due to distortions of the director field) and of a magnetic part (taking into account the interaction of the nematic with the external magnetic field), hence $F_{\text{nem}} = F_{\text{elast}} + F_{\text{mag}}$. The elastic free energy density follows from the Oseen-Zöcher-Frank expression [12–14].

$$F_{\text{elast}} = \frac{1}{2} K_{11} (\text{div} \ n)^2 + \frac{1}{2} K_{33} (\n \times \text{curl} \ n)^2. \quad (2)$$

In (2) $K_{11}$ and $K_{33}$ denote the elastic constants for splay and bend deformations in the nematic. Due to the restriction to planar director fields according to (1) there are no twist deformations and the elastic constant $K_{22}$ does not enter the calculations.

The magnetic free energy density couples the director $n$ to the magnetic field $\mathbf{H}$ via the anisotropy of the magnetic susceptibility $\Delta \chi$ ($\mu_0$ means the magnetic field constant).

$$F_{\text{mag}} = -\frac{1}{2} \mu_0 \Delta \chi (n \cdot H)^2. \quad (3)$$

When inserting the ansatz for the planar director field (1) into (2) and (3), we obtain the free energy density $F_{\text{nem}}$ of the nematic phase.

$$F_{\text{nem}} = \frac{1}{4} (K_{11} + K_{33}) (\Phi_x^2 + \Phi_y^2) + \frac{1}{4} (K_{33} - K_{11}) (\Phi_x^2 - \Phi_y^2) \cos 2\Phi$$

$$+ \frac{1}{2} (K_{33} - K_{11}) \Phi_x \Phi_y \sin 2\Phi - \frac{1}{4} \mu_0 \Delta \chi H_0^2 (1 + \cos 2\Phi). \quad (4)$$

In (4) $\Phi_x$ and $\Phi_y$ denote partial derivatives of the tilt angle with respect to the spatial coordinates. The energy of the defect core $F_{\text{core}}$ will be discussed separately in Section IV.

The director configuration for the planar soliton, which minimizes the energy of the nematic phase, follows as a solution of the corresponding Euler-Lagrange equation

$$\frac{\delta F_{\text{nem}}}{\delta n_i} \equiv \frac{\partial F_{\text{nem}}}{\partial n_i} - \partial_j \left( \frac{\partial F_{\text{nem}}}{\partial (\partial_j n_i)} \right) = 0. \quad (5)$$

The resulting equation for the tilt angle field $\Phi(x, y)$ can be written in the following form
\[ \Phi_{xx} + \Phi_{yy} + K \left[ \partial_x (\Phi_x \cos 2\Phi) - \partial_y (\Phi_y \cos 2\Phi) \right] \\
+ K \left[ \partial_x (\Phi_y \sin 2\Phi) + \partial_y (\Phi_x \sin 2\Phi) \right] + K (\Phi_x^2 - \Phi_y^2 - 2\Phi_x \Phi_y) \sin 2\Phi \\
- \frac{\mu_0 \Delta \chi H_0^2}{K_{11} + K_{33}} \sin 2\Phi = 0, \quad (6) \]

where

\[ K = \frac{K_{33} - K_{11}}{K_{11} + K_{33}} \]

is the elastic anisotropy.

**B. Boundary conditions**

The boundary conditions are an essential feature of the planar solitons. As discussed above, the defect structure is surrounded by a homogeneous director field and by a planar Néel wall. According to the choice of our Cartesian coordinate frame (Figs. 1 and 2) the tilt angle should be zero at \( y = \pm y_0 \), where \( y_0 \) is the half width of the Néel wall. Additionally, it should glue smoothly to the homogeneous orientation. Thus the boundary conditions in the \( y \) direction (perpendicular to the magnetic field) are given by

\[ \Phi(x, y = y_0) = 0, \quad \Phi(x, y = -y_0) = \pm \pi, \quad \Phi_y(x, y = \pm y_0) = 0, \quad (7) \]

where \( \pm \pi \) is for the positive and negative soliton, respectively.

In the \( x \) direction (parallel to the magnetic field), the director field at \( x \leq 0 \) coincides with the planar Néel wall. For increasing \( x \) coordinate the domain wall structure is destroyed and the director field changes towards the homogeneous orientation, parallel to the magnetic field, which is reached at \( x_0 \). Hence,

\[ \Phi(x = 0, y) = \Phi_{\text{Neel}}(y), \quad \Phi(x = x_0, y) = 0. \quad (8) \]

It is important to note that the value of \( x_0 \) is yet unknown at this stage.

The function \( \Phi_{\text{Neel}}(y) \) describes the director inversion due to the planar Néel wall. It can be determined by solving the field equation (8) in one dimension. For \( x \leq 0 \) there is no dependence on the coordinate \( x \) and the field equation is simplified to

\[ (1 - K \cos 2\Phi) \Phi_{yy} + K \Phi_y^2 \sin 2\Phi - \frac{\mu_0 \Delta \chi H_0^2}{K_{11} + K_{33}} \sin 2\Phi = 0. \quad (9) \]

The center line of the cross section of the domain wall with the \( x-y \) plane coincides with the line \( x \leq 0, y = 0 \), with tilt angle \( \Phi = \pm \frac{\pi}{2} \) on it. Now, following the approach developed in our recent publication [10], we apply a polynomial expansion of the tilt angle up to third order in the distance \( y \) from the center line,

\[ \Phi_{\text{Neel}}(y) = \pm \frac{\pi}{2} + \frac{3\pi}{4} \frac{y}{y_0} \pm \frac{\pi}{4} \left( \frac{y}{y_0} \right)^3. \quad (10) \]

The different signs are valid for positive and negative solitons, respectively. Due to the choice of the coefficients in the expansion (10), the boundary conditions (7) are fulfilled. With the
approximate expression (10) for $\Phi_{\text{Neel}}(y)$ we can satisfy (9) up to terms proportional to the first power of $y$. This fixes the half width $y_0$ of the planar Néel wall,

$$y_0 = \frac{3\pi}{4H_0} \sqrt{\frac{K_{\text{Neel}}}{\mu_0 \Delta \chi}}, \quad K_{\text{Neel}} = \left(1 + \frac{32}{9\pi^2}\right) K_{33} - K_{11}. \quad (11)$$

It is of the order of the magnetic coherence length. (11) and (10) are used in (8), which now provides the boundary conditions in the $x$ direction.

The approximate solution (10) could be improved by taking a higher or der polynomial. If it is of the order $y^n$, then (9) can be satisfied up to terms proportional to $y^{n-2}$. In the present paper we shall restrict ourselves to cubic polynomials in $y$, which are sufficient to reveal our method of obtaining the approximate director field for the planar soliton.

### III. TILT ANGLE FIELD FOR PLANAR SOLITONS

Our strategy for solving the non-linear partial differential equation (3) for the tilt angle $\Phi(x, y)$ proceeds in two steps. First we apply the polynomial expansion of the tilt angle field in the $y$ coordinate. After separating the $y$ dependence, we are left with a set of ordinary differential equations which is solved both numerically and, approximately, analytically. Of course, the polynomial expansion in $y$ must satisfy the boundary conditions (7). Therefore, up to third order (in congruence with the expansion for the Néel wall (10)) it reads

$$\Phi(x, y) = \left( \pm \frac{\Phi_0(x)}{y_0} + C(x) y \right) (y \mp y_0)^2 \mod \pi, \quad \text{for } y \geq 0, \ y \leq 0 \ \text{resp.} \quad (12)$$

The polynomial expansion (12) contains two unknown functions $\Phi_0(x)$ and $C(x)$ that depend on the $x$ coordinate. We can derive boundary conditions for them by inserting (12) into (8). This yields (for the positive solitons)

$$\Phi_0(x = 0) = \frac{\pi}{2}, \quad \Phi_0(x = x_0) = 0, \quad (13)$$

$$C(x = 0) = \frac{\pi}{4y_0^2}, \quad C(x = x_0) = 0. \quad (14)$$

Our ansatz (12) is continuous everywhere apart from the $x$ axis ($y = 0$). When crossing the $x$ axis between $x = 0$ and $x = x_0$, a jump in the director orientation from $+\Phi_0(x)$ to $-\Phi_0(x)$ occurs. This is connected to the physical singularity of the disclination line in the center of the defect. Most significantly, due to the influence of the external magnetic field the cross-section of the defect core is no more a point-like object in the $x$-$y$ plane, but it is extended to a segment of a straight line of length $x_0$. However, although the core of the defect is now strip-like (if we take into account the $z$ direction), one can define its center line. It is located at $x = x_d$, where $\Phi_0(x = x_d) = \frac{\pi}{4}$, which gives the largest jump (equal to $\frac{\pi}{2}$) in the director orientation at $y = 0$. At $x \leq 0$ there is no physical singularity, because $\Phi_0 = -\frac{\pi}{2}$ is equivalent to $\Phi_0 = +\frac{\pi}{2}$.

The discontinuity of (12) at $y = 0$ reflects the fact that the continuum approach is no more valid close to the defect core, where strong gradients of the orientational order are apparent. On a molecular length scale around the core the mesoscopic director looses its
physical significance as the average molecular orientation. Remarkably, although when using the director approach we cannot determine the orientational order within the defect core, our investigation gives hints on a possible elongated shape of the core of the disclination line in the presence of the magnetic field. The extension of the defect core (i.e. the actual value of $x_0$) can only be determined when including the core energy into the investigation. This will be performed in the following section.

We now proceed by inserting the third order polynomial expansion (12) into the equation (6). By comparison of the coefficients for the first two powers in the $y$ coordinate (i.e. $y^0, y^1$) we obtain two ordinary differential equations for the unknown expansion coefficients $\Phi_0(x)$ and $C_0(x)$. It is convenient to change to a set of dimensionless variables by measuring all length scales in units of $y_0$, $x = y_0 \bar{x}$, $\Psi = 2 \Phi_0$, $\Gamma = y_0^3 C$.

We also introduce the notation

$$\frac{1}{\eta^2} = 1 + \left(1 + \frac{9\pi^2}{16}\right) \mathcal{K}.$$  

The equations for $\Psi$ and $\Gamma$ have the following form

$$\begin{align*}
\frac{1}{2} (1 + \mathcal{K} \cos \Psi \right) \Psi'' + (1 - \mathcal{K} \cos \Psi \right) (\Psi - 4 \Gamma) - \mathcal{K} \left(\frac{1}{4} \Psi'^2 - (\Gamma - \Psi)^2 \right) \sin \Psi \\
+ 2 \mathcal{K} (\Gamma' - \Psi') \sin \Psi + 2 \mathcal{K} (\Gamma - \Psi) \Psi' \cos \Psi \\
- \mathcal{K} (\Gamma - \Psi) \Psi' \sin \Psi - \frac{1}{\eta^2} \sin \Psi = 0,
\end{align*}$$

and

$$\begin{align*}
\frac{1}{2} (1 + \mathcal{K} \cos \Psi \right) (\Gamma'' - \Psi'') - \frac{1}{2} \mathcal{K} (\Gamma - \Psi) \Psi'' \sin \Psi + 3 (1 - \mathcal{K} \cos \Psi \right) \Gamma \\
+ \mathcal{K} (\Gamma - \Psi) (\Psi - 4 \Gamma) \sin \Psi - \frac{1}{2} \mathcal{K} \left(\Psi' (\Gamma' - \Psi') - 2 (\Gamma - \Psi) (\Psi - 4 \Gamma) \right) \sin \Psi \\
+ \mathcal{K} (\Psi' - 4 \Gamma') \sin \Psi - \mathcal{K} (\Gamma - \Psi) (\Psi - 4 \Gamma) \cos \Psi \\
+ 2 \mathcal{K} (\Gamma - \Psi) (\Gamma' - \Psi') \cos \Psi - 2 \mathcal{K} \Psi' (\Gamma - \Psi)^2 \sin \Psi \\
- \mathcal{K} \Psi' (\Gamma - \Psi)^2 \cos \Psi + 2 \mathcal{K} \left(\Gamma - \Psi \right) (\Gamma' - \Psi') + \frac{1}{2} \Psi' (\Psi - 4 \Gamma) \right) \cos \Psi \\
- \mathcal{K} \left(\Gamma - \Psi \right) (\Gamma' - \Psi') + \frac{1}{2} \Psi' (\Psi - 4 \Gamma) \right) \sin \Psi - \frac{1}{\eta^2} (\Gamma - \Psi) \cos \Psi = 0.
\end{align*}$$

In (16) and (17) ' denotes derivatives with respect to the dimensionless variable $\bar{x}$.

The set of ordinary differential equations (16) and (17) becomes much simpler for the one-constant approximation ($\mathcal{K} = 0$). In this particular case the equations above are equivalent to the following ones

$$\begin{align*}
\Psi'' &= 8 \Gamma - 2 \Psi + 2 \sin \Psi, \\
\Gamma'' &= 2 \Gamma - 2 \Psi + 2 (\Gamma - \Psi) \cos \Psi + 2 \sin \Psi.
\end{align*}$$

Nevertheless, we shall analyse the set (16), (17). It turns out that a numerical solution and, if $\mathcal{K}$ is not too large, also an approximate analytical solution can be obtained.
According to (13) and (14) the boundary conditions (for positive solitons) now read (with $x_0 = x_0/y_0$)

$$\Psi(x = 0) = \pi, \quad \Psi(x = x_0) = 0, \quad (20)$$

$$\Gamma(x = 0) = \frac{\pi}{4}, \quad \Gamma(x = x_0) = 0. \quad (21)$$

Eqs. (16), (17), (20), (21) define a standard two-point boundary value problem. It can be solved numerically, for instance by a shooting method [18,19,11]. Satisfying the boundary conditions at $x = 0$, the ordinary differential equations (16), (17) are integrated numerically up to $x_0$. The integration constants are adapted iteratively in order to minimize the discrepancy between the numerical solution and the boundary conditions at $x_0$. For obtaining solutions for $\Psi(x)$ and $\Gamma(x)$ we used a computer code from Numerical Recipes [11]. Our calculations were performed for parameters corresponding to the liquid crystalline materials $N$-(p-methoxybenzylidene)-p- butylaniline (MBBA) and $p$-azoxyanisole (PAA) (see section IV). In these cases the numerical solution almost coincides with the approximate analytical solution presented below.

An approximate analytical solution of (16), (17) can be achieved, which turns out to be quite accurate, as being revealed by a comparison with the numerical solutions. We start from the observation that the free energy density of the defect core, which corresponds to a disordered phase, is much higher than the typical elastic energy of the nematic. Therefore we expect that the core size $x_0$ is small in comparison with the half-width of the Néel wall $y_0$, i.e. $x_0 = x_0/y_0 \ll 1$. Furthermore, $\Psi$ and $\Gamma$ change by a finite amount on the interval $[0, x_0]$, namely by $\pi$ or $\frac{\pi}{4}$, respectively. Therefore, the derivatives $\Psi'$, $\Gamma'$ are of the order $\pi/x_0$. They are much larger than $\Psi$ and $\Gamma$. One cannot a priori exclude that also the second order derivatives are large, of the order $\pi/x_0^2$. The approximation consists of keeping in (16), (17) the leading terms only. Then (16) reduces to

$$\left(1 + \overline{K} \cos \Psi \right) \Psi'' - \frac{1}{2} \overline{K} \Psi'^2 \sin \Psi = 0, \quad (22)$$

which can immediately be integrated yielding

$$\left(1 + \overline{K} \cos \Psi \right)^{1/2} \Psi' = \text{const.} \quad (23)$$

In the same approximation (17) simplifies to

$$\left(1 + \overline{K} \cos \Psi \right) \left(\Gamma'' - \Psi''\right) - \overline{K} \Psi' \left(\Gamma' - \Psi'\right) \sin \Psi$$

$$- \frac{1}{2} \overline{K} \left(\Gamma - \Psi\right) \Psi'^2 \cos \Psi - \overline{K} \left(\Gamma - \Psi\right) \Psi'' \sin \Psi = 0. \quad (24)$$

In addition to the smallness of $x_0$ one can also exploit the fact that the elastic anisotropy $\overline{K}$ can be rather small. For example, for MBBA its value is 0.11, while for PAA it is 0.42. Moreover, in (22), (24) $\overline{K}$ is multiplied by the sinus or cosinus of $\Psi$ – this effectively diminishes the significance of the terms proportional to $\overline{K}$ even further. Therefore, it is natural to look for solutions of (22), (24) in the form of an expansion into powers of $\overline{K}$. Up to first order in $\overline{K}$ we obtain

$$\Psi = \pi \left(1 - \frac{x}{x_0}\right) - \frac{1}{2} \overline{K} \sin \left[\pi \left(1 - \frac{x}{x_0}\right)\right] + \mathcal{O}(\overline{K}^2), \quad (25)$$
\[ \Gamma = \frac{\pi}{4} \left( 1 - \frac{x}{x_0} \right) - 2K \sin \left[ \frac{\pi}{4} \left( 1 - \frac{x}{x_0} \right) \right] \\
+ \frac{3\pi K}{8} \left( 1 - \frac{x}{x_0} \right) \left( 1 + \cos \left[ \frac{\pi}{4} \left( 1 - \frac{x}{x_0} \right) \right] \right) + O(K^2). \]  

(26)

A comparison with the numerical solutions of equations (22), (24) shows that the functions in (23), (26) yield very good approximations up to \( K = 0.6 \).

**IV. LENGTH OF THE DEFECT CORE**

Up to this stage, the length of the planar soliton \( x_0 \) (or, equivalently, \( \bar{x}_0 = x_0/y_0 \)) is unknown. We fix it by minimizing the total free energy, which includes the elastic and magnetic energy of the nematic phase as well as the energy of the defect core.

Let us first calculate the total nematic energy \( F_{\text{nem}} \) (per unit length along the \( z \) axis) for the soliton extending over the rectangle \( 0 \leq x \leq x_0, -y_0 \leq y \leq y_0 \), which contains the core of the defect at \( y = 0 \). Outside this rectangle there is the planar Néel wall at \( x \leq 0, -y_0 \leq y \leq y_0 \), and the homogeneous director orientation parallel to the external magnetic field along the three remaining sides of the rectangle. Therefore the rectangle contains the total elastic and magnetic energy of the distorted nematic due to the presence of the defect. It is given by the integral

\[ F_{\text{nem}} = 2 \int_0^{x_0} dx \int_0^{y_0} dy \ F_{\text{nem}}[\Phi(x, y)], \]  

(27)

where \( F_{\text{nem}} \) is given by (4). For the tilt angle \( \Phi(x, y) \) we use the approximate solution according to (12), (15), (25) and (26). The integrals in (27) can be calculated by help of a computer algebra system (e.g., MAPLE). The result has the following form

\[ F_{\text{nem}} = \frac{1}{2} (K_{11} + K_{33}) \left[ \frac{0.58}{x_0} - 0.72 \bar{x}_0 + K \left( \frac{0.19}{x_0} + 0.93 - 11.69 \bar{x}_0 \right) \right]. \]  

(28)

The terms proportional to \( 1/x_0 \) stem from elastic energy terms in \( F_{\text{nem}} \) proportional to \( \Phi_x^2 \). Due to these terms the elastic energy of a defect with a point-like core would be infinite, because for such a defect \( \bar{x}_0 = 0 \).

The expression (28) would suggest that \( \bar{x}_0 \) should be as large as possible – then \( F_{\text{nem}} \) would be minimal. In fact, this is not the case, due to the very large free energy stored in the defect core, where local transitions into disordered phases may occur. Let us perform an estimate of this core energy. (Again, it is understood that we consider the energy per unit length along the \( z \) axis.) The energy of the core is due to large gradients in the orientational order, which appear on a molecular length scale. Therefore it cannot be expressed in terms of the mesoscopic director field, but it is related to the molecular interaction potential across the discontinuity in the tilt angle on the segment \( 0 \leq x \leq x_0 \) of the \( x \) axis. This molecular interaction energy is small at the beginning and at the end of the core where the molecules on both sides of the segment are almost parallel. However, inside the core the molecules can even be perpendicular to each other. In this latter case the discontinuity of the tilt angle is
equal to \( \pi \), and the separation of centers of mass of the molecules is of the order \( \frac{\sigma_0}{\sqrt{2}} \) where \( \sigma_0 \) denotes the molecular length. In the present paper we shall be satisfied with a rough estimate obtained by assuming that the core energy density is given by (14), when all terms are neglected except for \( \frac{1}{4} (K_{11} + K_{33}) \Phi_y^2 \), with \( \Phi_y \approx \frac{\pi}{\sqrt{2}} \). The width of the core is taken to be of the order \( \frac{\sigma_0}{\sqrt{2}} \). This yields an estimate for the total energy of the core

\[
F_{\text{core}} \approx \frac{1}{4} (K_{11} + K_{33}) \Phi_y^2 x_0 \sigma_0 \frac{\pi^2}{\sqrt{2}} = \frac{\pi^2}{8\sqrt{2}} (K_{11} + K_{33}) \frac{y_0}{\sigma_0} x_0.
\]

The total energy of the planar soliton is then \( F = F_{\text{nem}} + F_{\text{core}} \). We now insert (28), (29) and then minimize \( F \) with respect to the reduced core length \( x_0 \). It is easy to find out that the \( x_0 \) corresponding to the minimum total energy is given by

\[
x_0^2 = \frac{0.58 + 0.19 \frac{\pi y_0}{\sigma_0}}{1.74 y_0/\sigma_0 - 0.72 - 11.69}.
\]

Let us compute \( x_0 \) for particular nematic materials. For \( N-(p\text{-methoxybenzylidene})p\text{-buthylaniline} \) (MBBA) at 25°C (17) the elastic constants are \( K_{11} = 6.0 \times 10^{-12} \) N and \( K_{33} = 7.5 \times 10^{-12} \) N. The magnetic anisotropy is \( \mu_0 \Delta \chi = 9.7 \times 10^{-8} \) Vs/Am, the molecular length \( \sigma_0 = 30 \) Å. The magnetic field strength \( H_0 \) is chosen 500 Oersted, according to a magnetic flux density \( B_0 \equiv \mu_0 H_0 = 0.05 \) T. Then, the elastic anisotropy is \( K = 0.11 \). Equation (11) yields \( y_0 = 3900 \) Å. Finally, \( x_0^2 \approx 0.0027 \), and \( x_0 \approx 202 \) Å.

For \( p\text{-azoxyanisole} \) (PAA) at 120°C (17) the elastic constants are \( K_{11} = 7.0 \times 10^{-12} \) N and \( K_{33} = 17.0 \times 10^{-12} \) N. The magnetic anisotropy is \( \mu_0 \Delta \chi = 12.1 \times 10^{-8} \) Vs/Am, the molecular length \( \sigma_0 = 20 \) Å. The magnetic field strength \( H_0 \) is again chosen 500 Oersted. The elastic anisotropy is \( K = 0.42 \), \( y_0 = 6850 \) Å, and finally \( x_0^2 \approx 0.0011 \), \( x_0 \approx 229 \) Å.

We notice that in both examples \( x_0^2 \) is rather small, indeed. This is consistent with the assumption leading to the approximate solutions (25), (26). The resulting physical length of the core \( x_0 \) is relatively large and it probably could be seen in appropriate experiments. The dependence of the nematic, core and total energies on the reduced length of the defect core is plotted in Figs. 3 (MBBA) and 4 (PAA).

With the determination of the reduced core length \( x_0 \) the calculation of the director field for the planar soliton is completed. The tilt angle field is shown in Figs. 5 (positive soliton) and 6 (negative soliton). The core line at \( y = 0 \) is clearly visible by the jump of the tilt angle. However, this picture is somewhat misleading, because it does not take into account that the director is an object without arrowhead. For instance, at \( \pi = 0 \), \( \frac{\pi}{2} = 0 \pm \) there is a jump by \( \pi \) which in fact means an orientational change of zero angle, exactly the same as for \( \pi = \pi_0 = 0.052 \), \( y_0 = 0 \pm \). As already stated in the previous section, due to the periodicity of \( \pi \) for tilt angle changes the largest orientational jump occurs for \( \pi_0 = 0.025 \), \( y_0 = 0 \pm \), where the tilt angle is \( \pm \frac{\pi}{4} \). This point can be defined as the center of the core which is related to the original disclination line (in three dimensions).

These particular features become obvious from a lattice visualization of the director field, which is presented in Figs. 7 (positive soliton) and 8 (negative soliton). (In these figures the \( x \) and \( y \) dimensions are not proportionally scaled.) Rods of unitary length placed on the sites of a rectangular lattice indicate the local orientation. The dashed line means the defect core and the small circle marks the center of the core, according to the previous discussion.
V. REMARKS

1. The positive and negative planar soliton are distinguished by the boundary conditions (20) and (21), but not by the field equations. Therefore they cover exactly the same area, although their energy content is slightly different. The tilt angle field for the negative soliton $\Phi^- (x, y)$ is obtained from the positive soliton solution $\Phi (x, y)$ presented above by a sign inversion of the expansion coefficients: $\Phi_0^- (x) = -\Phi_0 (x)$ and $C^- (x) = -C (x)$.

2. Expression (30) reveals a rather interesting dependence of the reduced core length $x_0$ on the magnetic field $H_0$ which enters through $y_0$ (see (11)). For weak magnetic fields we have large $y_0$, hence $x_0$ is small and it tends to zero when the magnetic field vanishes. However, the physical length of the core is equal to $x_0 = y_0 \pi$ and it increases as $\frac{1}{\sqrt{H_0}}$ when the magnetic field decreases. The physical reason is that for a weaker magnetic field the distance over which the director field can be reoriented by a given angle is larger. In the case of planar solitons the required reorientation is such that the tilt angle changes from $\Phi_{\text{Neel}} (y)$ towards zero. Of course in this limit the width of the Néel domain wall (11) also increases, as $\frac{1}{H_0}$, hence faster. On the other hand, with increasing magnetic field $y_0$ decreases and $x_0$ increases. From inserting (11) into (30) it is noticed that formally there is a finite critical value for the magnetic field at which $x_0$ becomes infinite. For MBBA the dependence of the reduced and physical core length $x_0$ and $x_0$ on the reduced magnetic field $h_0 \equiv H_0 \text{[Oersted]/500}$ is

$$\Phi_0 = 0.55 \sqrt{\frac{h}{112.8 - h}}, \quad \frac{x_0[A]}{202} = \frac{10.57}{\sqrt{h (112.8 - h)}} \quad (31)$$

which yields a critical reduced magnetic field $h_c = 112.8$, corresponding to a critical flux density of 5.64 T. (Analogous calculations for PAA give a somewhat smaller critical flux density of 5.3 T.) However, it should be remembered that Eq. (31) has been derived under the assumption that $\Phi_0$ is small, so it may become wrong well before reaching the critical value of the magnetic field.

To conclude, we found an approximate solution for the director configuration in planar solitons in nematics. It is continuous everywhere apart from a strip of finite width. This points out the possibility of an elongated shape of the defect core in disclination lines due to an external magnetic field.
