Chemiluminescent probes for imaging H$_2$S in living animals$^+$

J. Cao, R. Lopez, J. M. Thacker, J. Y. Moon, C. Jiang, S. N. S. Morris, J. H. Bauer, P. Tao, R. P. Mason and A. R. Lippert*

Hydrogen sulphide (H$_2$S) is an endogenous mediator of human health and disease, but precise measurement in living cells and animals remains a considerable challenge. We report the total chemical synthesis and characterization of three 1,2-dioxetane chemiluminescent reaction-based H$_2$S probes, CHS-1, CHS-2, and CHS-3. Upon treatment with H$_2$S at physiological pH, these probes display instantaneous light emission that is sustained for over an hour with high selectivity against other reactive sulphur, oxygen, and nitrogen species. Analysis of the phenol/phenolate equilibrium and atomic charges has provided a generally applicable predictive model to design improved chemiluminescent probes. The utility of these chemiluminescent reagents was demonstrated by applying CHS-3 to detect cellularly generated H$_2$S using a multi-well plate reader and to image H$_2$S in living mice using CCD camera technology.

Introduction

Hydrogen sulphide (H$_2$S) is increasingly recognized as an important mediator of mammalian physiology and pathology, playing roles in vasorelaxation, angiogenesis, redox regulation, neuromodulation, lifespan, Huntington’s disease, Down syndrome, diabetes, and cancer. In mammals, endogenous H$_2$S is generated from cystathionine β-synthase (CBS), cystathionine γ-lyase (CSE), and 3-mercaptopyruvate sulphur transferase (3MST). Similar to its reactive cousins, nitric oxide (NO) and hydrogen peroxide (H$_2$O$_2$), H$_2$S mediates cellular function via direct chemical interaction with biological molecules and can have widely disparate effects that depend on concentration, tissue localization, and the molecular environment. For example, H$_2$S in colon cancer promotes tumour growth by stimulating angiogenesis and supporting cellular energetics, whilst H$_2$S in prostate cancer slows cell growth, disrupts androgen receptor transactivation, and reduces angiogenesis by inhibiting the function of hypoxia-inducible factor 1. Given the delicate site- and concentration-dependent actions of H$_2$S, easy methods for accurate spatiotemporal detection in living cells and animals are in urgent demand and promise to significantly contribute to an increased understanding of this reactive signalling molecule.

Common methods of H$_2$S detection, including the methylene blue assay, ion-selective electrodes, amperometric sensors, and gas chromatography, have varying strengths and weaknesses, but all generally fall short of being able to detect H$_2$S inside of intact living organisms. Fluorescent probes offer the ability to target specific analytes and there has been an explosion of recent activity in the development of dyes responsive to H$_2$S and its derivatives. Unfortunately, imaging endogenous H$_2$S remains rare, and often requires advanced confocal microscopy setups to allow precise same-cell tracking or two-photon excitation coupled with ratiometric imaging. This instrumentation is unavailable to many researchers, reducing the potential impact of these newly developed tools. Furthermore, there are few examples of in vivo imaging of H$_2$S and imaging deep mammalian tissue remains a frontier for H$_2$S detection. At the heart of the matter is a lack of sensitivity and depth penetration due to background autofluorescence, light scattering, photobleaching, and probe kinetics that requires long incubation times to accumulate signal. In order to address these technological challenges and develop tools to better elucidate the precise mechanisms of H$_2$S production and function, we have herein developed a series of selective and sensitive chemiluminescent probes for rapid imaging of H$_2$S in living animals.

Triggered chemiluminescence emission can provide a highly sensitive readout of biological analytes. Chemiluminescence
doesn't require light excitation, thereby drastically reducing background from autofluorescence and photoactivation of azide functional groups. Whereas bioluminescence (chemiluminescence derived from living systems that express bioluminescent enzymes such as luciferase) has found wide application for preclinical analysis of biological parameters using genetically modified organisms, small molecule chemiluminescence can be used with wild-type animals and opens up exciting opportunities for clinical imaging. Recently, there have appeared select examples of chemiluminescent agents for the detection of H2S in vitro. Although quite promising, the need for enzymatic additives and alkaline conditions introduces cytotoxicity and can potentially release sulphide from proteins and other base-labile sulphur pools, ultimately hindering their potential for whole animal imaging.

To overcome these issues and expand the scope of chemiluminescent detection technology for small molecule biological analytes, we focused on using sterically stabilized 1,2-dioxetane systems to develop a series of new chemiluminescent H2S probes that display instantaneous light production under biologically compatible conditions. Sterically stabilized dioxetanes have been used for femtogram detection of enzymatic analytes and have demonstrated potential for in vivo imaging. We introduce three first generation chemiluminescent H2S probes, CHS-1, CHS-2, and CHS-3, derived from sterically stabilized spiroadantamantane 1,2-dioxetane scaffolds modified with self-immolative 4-azidobenzyl carbonates as the H2S response site (Scheme 1). This article reports their synthetic preparation, optical response and selectivity for H2S, experimental and computational mechanistic investigations of their chemiluminescent response, detection of cellular H2S using a multi-well plate reader, and a noteworthy demonstration of whole animal chemiluminescent imaging of H2S.

Results and discussion
Design and synthesis of CHS-1, CHS-2, and CHS-3
The CHS probe series was designed such that chemiluminescent emission would be initiated by the H2S-mediated reduction of the azide group, followed by self-immolative carbonate cleavage yielding the free phenolate bearing the 1,2-dioxetane (Scheme 1). The negatively charged phenolate will emit light spontaneously upon decomposition via an intramolecular chemically initiated electron exchange luminescence (CIEEL) mechanism. This newly produced light can be observed directly or by transfer of its energy to acceptor molecules like quantum dots, rhodamine, or fluorescein. In our studies, we employ a commercially available Emerald II Enhancer solution that consists of a cationic polymer and a dye with similar photophysical properties to fluorescein. The polymer reduces water-induced quenching by providing a hydrophobic environment for the chemiluminescent reaction and the dye effectively red shifts the luminescence emission making it more amenable for biological imaging applications.

By adapting a literature procedure, we optimized an efficient and modular synthetic route to access the probes CHS-1, CHS-2, and CHS-3 (Scheme 2). First, unsubstituted, fluorinated, and chlorinated 3-methoxybenzaldehyde derivatives 1a-c were reacted with trimethyl orthoformate in the presence of p-toluenesulfonic acid to give acetals 2a-c. These acetals were subjected to triethyl phosphite and boron trifluoride diethyl etherate at 0 °C, which afforded the diethyl methoxy (3-methoxyphenyl) methyl phosphonates 3a-c. Next, enol ethers 4a-c were obtained through Horner–Wadsworth–Emmons reaction by treating phosphonates 3a-c with 6-BuLi and 2-adamantanone. Nucleophilic demethylation using sodium ethanethiolate provided the phenols 5a-c. The activated ester 6, prepared according to analogous literature procedures, was coupled to the phenols to provide 7a-c, azide-bearing precursors to the final 1,2-dioxetanes. Finally, a [2 + 2] cycloaddition with singlet oxygen was accomplished by bubbling oxygen through a solution of 7a-c and the sensitizer Rose bengal with visible light irradiation, delivering the chemiluminescent probes CHS-1, CHS-2, and CHS-3.
Response and selectivity
With the first three CHS probes in hand, we proceeded to measure their luminescent responses to H$_2$S using an F-7000 Hitachi spectrophotometer. At pH 7.4, treatment of the CHS probes with H$_2$S resulted in instantaneous luminescent emission that increased over a course of 10 minutes in a dose-dependent manner (Fig. 1). Addition of the fluorescein-based Emerald II Enhancer provided a red-shifted peak centred at 545 nm compared to the 470 nm emission of the phenolate (Fig. 1, insets). Under these physiologically relevant conditions, we observed an increase in the integrated luminescent response to H$_2$S from CHS-1 to CHS-2 to CHS-3, giving 5-fold, 4-fold, and 12-fold turn-on responses respectively. It should be noted that no background corrections were performed and the values in Fig. 1 are direct instrumental values to provide an accurate comparison between probes. At pH 10, CHS-1 provided the highest chemiluminescence intensity and response, giving a 7-fold increase in photon emission in the first 10 minutes after adding 200 $\mu$M H$_2$S (Fig. S1†). Under these alkaline conditions, the H$_2$S-triggered chemiluminescent emissions of the fluorinated CHS-2 and chlorinated CHS-3 were lower than CHS-1. The background signal also increases with CHS-2 and CHS-3, reducing the relative increases over control to 2-fold and 3-fold respectively. A key advantage of these probes is that they display an immediate concentration-dependent emission of light that persists for over an hour (Fig. S2†), an ideal property for the high-throughput detection and imaging of H$_2$S generated in biological environments.

We next tested the selectivity of CHS-1, CHS-2, and CHS-3 for H$_2$S against other biologically relevant reactive sulphur, oxygen, and nitrogen (RSON) species. The response of CHS-1 to 200 $\mu$M Na$_2$S in 20 mM HEPES buffered to pH 7.4 was tested against other RSON species by adding 5 mM reduced glutathione (GSH), 1 mM l-cysteine and homocysteine, and 200 $\mu$M of S-nitrosogluthathione, sulfito (SO$_3^{2-}$), hydrogen peroxide (H$_2$O$_2$), hypochlorite (OCl$^-$), tert-butyl hydroperoxide (tertBuOOH), nitroxy1 (HNO), nitric oxide (NO), and nitrite (NO$_2^-$). None of the species tested displayed significant increases in luminescence intensity over the blank control (Fig. 2a). Additionally, the response to Na$_2$S was minimally perturbed by the presence of physiological levels of GSH, l-cysteine, and homocysteine. We observed similar results when CHS-2 and CHS-3 were evaluated for their selectivity in 20 mM HEPES at pH 7.4 (Fig. 2b and c).

These response and selectivity data demonstrate that CHS-1, CHS-2, and CHS-3 are able to detect H$_2$S at physiologically relevant pH with minimal interference from competing analytes.

Mechanistic studies of chemiluminescent H$_2$S detection
We next sought to understand the factors that lead to increased light production and optimized response for 1,2-dioxetane chemiluminescent probes. First, we investigated the role of the phenol/phenolate equilibrium. Since the measurement of the $pK_a$ of the phenolate dioxetane products of the CHS probes is complicated by their rapid chemiluminescent decomposition, we used the reported experimental values of phenol, 2-fluorophenol, and 2-chlorophenol as an approximation.47 We plotted the integrated chemiluminescent emission of CHS-1, CHS-2, and CHS-3 in response to 200 $\mu$M Na$_2$S at pH 7.4 and pH 10 (Fig. 3a and b) against the experimental $pK_a$ values for phenol, 2-fluorophenol, and 2-chlorophenol (Fig. 3c and d). The H$_2$S-stimulated emission intensity at pH 7.4 displays an increasing trend with increased phenol acidity, indicating that ionization of the phenol is critical to attaining good luminescent response under these conditions (Fig. 3c). On the other hand, there is no clear correlation with phenol $pK_a$ and the chemiluminescent response at pH 10 (Fig. 3d). We further investigated the nature of the chemiluminescent emission by performing quantum chemistry calculations on the phenolate structures released from CHS-1, CHS-2, and CHS-3 after reaction with Na$_2$S (Tables S1–S3†). Geometries were optimized using density functional theory (DFT) at the B3LYP/6-311+G(d,p) level of theory, and the charge on each atom was...
calculated using an electrostatic potential (ESP) model at the M06/6-311+G(d,p) level of theory. All calculations were carried out with the integral equation formalism polarizable continuum model (IEF-PCM) in water as solvent using the Gaussian 09 program package. While we found no correlation between the charge on the phenolic oxygen (O8) and the chemiluminescent response at pH 7.4 (Fig. 3f), an excellent correlation ($R^2 > 0.99$) was observed with the response at pH 10 (Fig. 3f). ESP charge calculations performed with B3LYP and ωB97XD functionals also provided good correlations ($R^2 > 0.97$) of the O8 charge and the chemiluminescent response at pH 10 (Fig. S3†). These data indicate that at lower pH, the chemiluminescent emission is governed by the equilibrium between the protonated phenol and unprotonated phenolate oxygen, and are in agreement with previous observations.49 CHS-3 is the most readily ionized and therefore shows the highest chemiluminescent emission. On the other hand, at pH 10 the phenolate species dominates for all three deprotected dioxetanes and the efficiency of chemiluminescent emission is predicted by the more negative O8 charge density, probably due to an increased propensity towards initiation of the first intramolecular electron transfer step of CIEEL.49,50 These data reveal trends that, when taken together, provide a powerful predictive model for the design of improved chemiluminescent reagents.

Using CHS-3 to detect cellular H$_2$S

Our results show that CHS-3 provides the most robust light emission at physiological pH when compared to CHS-1 and CHS-2. We therefore examined the ability of CHS-3 to detect cellular H$_2$S production in human lung adenocarcinoma epithelial cells (A549). These cells express the enzyme cystathionine γ-lyase (CSE),31 which can utilize homocysteine (Hcy) as a substrate for H$_2$S production. We first demonstrated the ability of CHS-3 to detect exogenous Na$_2$S in a multi-well plate reader format (Fig. 4a), and determined an estimated detection limit (blank control + 3 S.D.) of 5.4 μM. We then incubated A549 cells with Hcy, a substrate for the enzyme CSE. This resulted in...
Fig. 4 Detection of cellular H2S using a multi-well plate reader. (a) Luminescent responses of 40 μM CHS-3 and 0, 25, 50, 100, and 200 μM Na2S in 20 mM HEPES buffer (pH 7.4) containing 20% Emerald II Enhancer. (b) A549 cells were treated with a vehicle control (Cont), 200 μM Hcy (Hcy), or 200 μM Hcy after being pre-treated with 200 μM PAG (Hcy + PAG) for 20 min. 20 min after incubating with Hcy or vehicle, the cells were washed and treated with 40 μM CHS-3 and 125 μL Emerald II Enhancer. The reported values represent the average luminescent intensity of replicate experiments (n = 12, p = 0.044). Error bars represent ± S.E.M.

~10% increase (n = 12, p = 0.044) in luminescent emission from CHS-3 compared with vehicle treated cells (Fig. 4b). Pre-incubation with the CSE inhibitor Nα-L-propargylglycine (PAG) before adding Hcy attenuates signal observed from CHS-3. Although the observed increase is small, it is statistically significant and the efficacy of CHS-3 for endpoint detection of H2S generated by whole cells at physiological pH is an important advance that sets the stage for imaging H2S in living animals.

In vivo imaging of H2S using CHS-3

We next investigated the ability of CHS-3 to image H2S at physiological pH using an IVIS Spectrum. An opaque 96-well plate was loaded with 0, 25, 50, 100, and 200 μM Na2S in 20 mM HEPES buffer (pH 7.4) containing 20% Emerald II Enhancer. CHS-3 was added at 40 μM and imaged to reveal a clear increase in luminescence intensity with increasing H2S concentrations (Fig. 5a). Averages of repeated experiments provide a good linear response in the range of 0–200 μM when imaged 30 s after exposure to H2S (Fig. 5b). We next applied a mouse carcass model to determine if CHS-3 would have sufficient light output to be observable through mammalian tissue. The carcasses of sacrificed SCID/BALB-C mice were injected with CHS-3 and either a vehicle control (Fig. S4a and b) or 0.4 μmol H2S (Fig. S4c and d) into the peritoneal cavity. An increase in luminescence could be clearly observed in the peritoneum of the carcass injected with H2S versus the carcass injected with the vehicle control.

Confident that light emission from CHS-3 was capable of significant tissue penetration, we finally sought to establish the ability of CHS-3 to image H2S in living animals. C6 brown mice were administered i.p. injections on one side of their peritoneal cavity. The skin was raised during injections to avoid puncturing internal organs. Images were acquired 30 s after injecting 0.08 μmol CHS-3 and either 0.4 μmol Na2S or a vehicle control (H2O) in 100 μL HEPES buffered at pH 7.4 containing 20% Emerald II Enhancer. The final concentration of Na2S in the injection was 4 mM. While vehicle control experiments produced modest signal (Fig. 5c), the mice that received Na2S treatments displayed robust emission of light that was easily detected through their tissue (Fig. 5d). Quantification of the total photon flux from replicate experiments (Fig. S5†) revealed ~4-fold increase (n = 3, p = 0.025) in the luminescence response in the Na2S treated mice versus vehicle controls (Fig. 5e). The agents were well tolerated and the mice showed no immediate outward signs of malaise. Taken together, these data provide a key milestone towards the development of a new class of in vivo imaging tools for investigating biological hydrogen sulphide.

Conclusions

We have designed and synthesized three 1,2-dioxetane chemiluminescent reaction-based H2S probes, CHS-1, CHS-2, and
CHS-3 that display immediate light emission upon reacting with H_{2}S at physiological pH, a significant advance for H_{2}S detection technology. These reagents provide a sensitive and selective detection platform for H_{2}S using spectrophotometers, multi-well plate readers, and IVIS Spectrum instruments. We have provided a computational and experimentally supported mechanistic framework that serves as a predictive model for multi-well plate readers, and IVIS Spectrum instruments. We treated with homocysteine at neutral pH, but also has the rare ability to image H_{2}S in living animals. While CHS-3 provides an exciting proof of principle for in vivo chemiluminescence imaging, we are currently engaged in improving the sensitivity and biocompatibility of chemiluminescent 1,2-dioxetane reagents for diverse applications, and anticipate that these new optimized systems will provide powerful whole animal imaging tools across a range of biological analytes and parameters.
