Abstract

In the context of un-oriented open string theories, we identify quivers whereby a Majorana mass for the neutron is indirectly generated by exotic instantons. We discuss two classes of (Susy) Standard Model like quivers, depending on the embedding of $SU(2)W$ in the Chan-Paton group. In both cases, the main mechanism involves a vector-like pair mixing through a non-perturbative mass term. We also discuss possible relations between the phenomenology of Neutron-Antineutron oscillations and LHC physics in these models. In particular, a vector-like pair of color-triplet scalars or color-triplet fermions could be directly detected at LHC, compatibly with $n - \bar{n}$ limits. Finally we briefly comment on Pati-Salam extensions of our models.

1 Introduction

Recently we have proposed the possibility that a Majorana mass term for the neutron could be indirectly generated by non-perturbative quantum gravity effects present in string theory: the exotic instantons [1, 2] In theories with open and un-oriented strings, instantons have a simple geometrical interpretation: they are nothing but Euclidean D-branes (a.k.a. E-branes) wrapping internal cycles of the compactification. ‘Gauge’ instantons are E-branes wrapping the same cycles as some D-branes present in the vacuum configuration. ‘Exotic’ stringy instantons are E-branes wrapping cycles different from those wrapped by the D-branes present in the background. For ‘gauge’

\[\text{E-mail: massimo.bianchi@roma2.infn.it}\]

\[\text{For the classification of instanton effects in strings theory see: [1]-[9] for world-sheet instantons in the heterotic string, [10]-[12] for E2-instantons in the Type IIA string, [13]-[15] for M2-brane and M5-brane instantons in M-theory, [16]-[18] for the D3-D(−1) system in type IIB, [19] for the effect of background fluxes on E2-instantons, [20] for E3-instantons in Type IIB theory. In [21] [22], instantons in Z3 orbifolds are discussed.}\]
instantons, a very natural and intuitive embedding of the ADHM data [3] is represented by open strings with at least one end on the E-branes. Exotic instantons admit a similar description that however escapes the ADHM construction in that – in the simplest and most interesting case – the moduli are purely fermionic. Non-perturbative effects generated by both ‘gauge’ and ‘exotic’ instantons are calculable in string inspired extensions of the (supersymmetric) Standard Model. Exotic instantons can break both anomalous axial symmetries and vectorial ones. Gauge instantons can break anomalous symmetries only.

Recall that in the SM only $B - L$ is non-anomalous. Baryon and Lepton numbers are separately anomalous and can be broken by non-perturbative finite-temperature instanton-like effects due to ‘sphalerons’ [24]. At low temperature, as in the present cosmological epoch, sphaleron effects are highly suppressed but $SU(2)$ EW ‘sphalerons’ play an important role during the early stages of the universe, up to the electro-weak phase transition. In the primordial thermal bath ($B - L$)-preserving transitions can be induced by sphalerons because of the thermal fluctuations in the weakly coupled plasma. They have only the net effect to convert $B$ to $L$ and vice versa: they cannot provide separate mechanisms for Baryogenesis or Leptogenesis without Physics Beyond the Standard Model [25]. As explicitly noticed by t’Hooft, these ($B - L$)-preserving transitions are suppressed by factors of order $10^{-120}$ and are thus absolutely impossible to detect in the laboratory [26]. (See also [27] for a classical textbook on these aspects).

On the other hand, ‘exotic’ instantons can break vector-like and non-anomalous symmetries too, and in principle they can be unsuppressed. This peculiar feature of exotic instantons can lead to interesting B- (or L-) and B-L violating physics testable in laboratories, such as a Majorana mass for the neutron and related $n - \bar{n}$ oscillations [1]. These effects can also dynamically propagate from the string scale to much lower energies, as shown in [1]. The possibility of an effective Majorana mass term for the neutron was firstly proposed by Majorana himself in [28]. Such a mass term could induce neutron-antineutron transitions, violating Baryon number, contrary to the predictions of the Standard Model [29]. The next generation of experiments is expected to test $PeV$ physics [30] [31] by improving the limits on the oscillation time to $\tau_{n-\bar{n}} \simeq 10^{10}$ s, two orders of magnitude higher than the current limits [32].

Let us suppose instead that such $n - \bar{n}$ oscillations be found in the next run of experiments: then it would be challenging to generate such an effect with a time-scale...
around $10^{10}$ s $\approx 300$yr without fast proton decay ($t_{p-limit} \simeq 10^{34}$ yr) or unsuppressed FCNC’s. The class of models that we consider seems to meet these requirements. Exotic instantons propagate the quantum gravity stringy effects to much lower scales, that can be as low as 1000 TeV.

The main purpose of the present paper is to clarify aspects of the mechanism proposed in [1] and to identify quiver theories leading to the interesting phenomenology introduced in [1]. The paper is organized as follows: in Section 2 we briefly review the main features of the models with Majorana mass terms for the neutron; in Section 3, we discuss the phenomenology related to neutron-antineutron oscillations, reviewing and extending our previous considerations and constraining the allowed region in parameter space, with particular attention to possible signatures at LHC; in Section 4 we briefly review the construction of (un-oriented) quiver theories; and identify SM-like (un-oriented) quivers for a Majorana neutron in Section 5 we discuss possible quantum corrections to the Kähler potential and D-terms as well as the role of susy breaking; in Section 6 we present our conclusions and a preliminary discussion of Pati-Salam extensions.

2 A simple class of models

The models we consider are based on D6-branes wrapping 3-cycles in $CY_3$ and giving rise to such gauge groups as $U(3) \times U(2) \times U(1) \times U(1)_\nu$ or $U(3) \times Sp(2) \times U(1) \times U(1)_\nu$. We will also need an $\Omega$-plane for local tadpole cancellation and $E2$-branes (instantons).

The un-oriented strings between the various stacks account for the minimal super-field content of the MSSM

$$Q_{i+1/3}^{i, \alpha} \quad L_{-1}^\alpha \quad U_{i, -4/3}^c \quad E_{i+2/3}^c \quad D_{i+2/2}^c \quad H_{u, +1}^\alpha \quad H_{d, -1}^\alpha$$

These interact via the super-potential

$$W = y_d H_d^\alpha Q_i^i D_i^c + y_l H_d^\alpha L_{-1}^\alpha E^c + y_u H_u^\alpha U_{i, -4/3}^c + \mu H_u^\alpha H_{i, -1}^\alpha$$

Flavour or family indices are understood unless strictly necessary. Note that $W$ preserves R-parity. The last term violates the continuous R-symmetry and can be generated by $E2$-branes (instantons) as discussed in [33, 34, 35] and reviewed later on.

We could also consider some of the possible perturbative R-parity breaking terms (see [36] for a review on the subject):

$$W_{RPV} = \lambda_{LLE} L^\alpha L_{-1}^\alpha E^c + \lambda_{LQD} L_{-1}^\alpha Q_i^i D_i^c + \lambda_{UDD} \epsilon^{ijk} U_i^c D_j^c D_k^c + \mu_{LH} H_u^\alpha H_{i, -1}^\alpha$$
Moreover, soft susy breaking terms can be generated by fluxes or other means, that produce scalar mass terms, Majorana mass terms for gaugini (zino, photino, gluini), trilinear $A$-terms, bilinear $B$-terms [37, 38].

In the first case, the hypercharge group $U(1)_Y$ is a combination of the four anomalous $U(1)$’s

$$U(3) \times U(2) \times U(1) \times U'(1) \simeq SU(3) \times SU(2) \times U(1)_3 \times U(1)_2 \times U(1) \times U'(1) \quad (4)$$

In fact the four $U(1)$’s can be recombined into $U(1)_Y$, $U(1)_{B-L}$ and two anomalous $U(1)$’s. In the other case, with gauge group $U(3) \times Sp(2) \times U(1) \times U'(1)$, one has

$$U(3) \times Sp(2) \times U(1) \times U'(1) \simeq SU(3) \times SU(2) \times U(1)_3 \times U(1) \times U'(1) \quad (5)$$

and $Y$ is a linear combination of 3 charges $q_{1,1',3}$.

The presence of anomalous $U(1)$’s is not a problem in string theory. A generalisation of the Green-Schwarz mechanism disposes of anomalies. In particular in the string-inspired extension of the (MS)SM under consideration, new vector bosons $Z'$ appear that get a mass via a St"uckelberg mechanism [40] and interact through generalized Chern-Simon (GCS) terms, in such a way as to cancel all anomalies [41, 42, 22].

If the relevant D-brane stacks intersect four rather than three times, i.e. $\# U(3) \cdot U(1) = 4$, a 4th replica $D' = D'_{f=4}$ of the three MSSM $D'_{j=1,2,3}$ appears. Moreover, compatibly with tadpole and anomaly cancellation, another chiral super-field $C^i = \frac{1}{2} \epsilon^{ijk} C_{jk}$ appears at the intersection of the two images of the $U(3)$ stack of $D6$-branes, reflecting each other on the $\Omega$-plane[4]

$$D'_{Y=+2/3}(B = -1/3) \quad \text{and} \quad C^i_{Y=-2/3}(B = -2/3) = \frac{1}{2} \epsilon^{ijk} C_{jk}$$

form a vector-like pair with respect to $SU(3)$. New perturbative Yukawa-like interactions involve $D'$ and $C$

$$W_1 = h_D Q'^i H_a D'_c$$

and

$$W_2 = h_C Q'^i Q^j C_{ij}$$

A non-perturbative mixing mass term

$$W_{exotic} = \frac{1}{2} M_0 \epsilon^{ijk} D'^i_c C_{jk}$$

Note that the first two ingredients – MSSM super-fields and R-preserving super-potential – have been widely explored in the literature, the additional vector-like pair and the $\Omega$-plane mark the main difference between our model, proposed in [1], and the ones already known.
Figure 1: Diagram inducing neutron-antineutron transitions through vector-like pair of
fermions $D', C$ (the white blob represent the non-perturbative mass term induced by
exotic instantons), an Higgsino, and a conversion of squarks into quarks through gaugini, like
zini or gluini.

is generated by non-perturbative $E2$-instanton effects. The relevant $E2$-brane (exotic
instanton) is transversely invariant under $\Omega$ and intersects the physical $D6$-branes,
as discussed in [1]. The non-perturbative mass scale is $\mathcal{M}_0 \sim M_S e^{-S_{E2}}$ with $M_S$
the string scale, $S_{E2}$ the $E2$ instanton action, depending on the closed string moduli
parameterizing the complexified size of the 3-cycle wrapped by the world-volume of
$E2$.

Integrating out the vector-like pair an effective super-potential of the form

$$W_{eff} = h_{D'} h_C \frac{1}{\mathcal{M}_0} Q^{ai}_i H^a Q^{j}_b^\beta F^{ij} \epsilon_{ijk}$$  (9)

is generated.

In this way, one can start with a theory preserving R-parity and have it broken
dynamically only through the non-renormalizable R-parity breaking operator (9).

In principle, one can also consider some explicit R-parity breaking terms, including
perturbative ones [3], but then one has to carefully study the dangerous effect of these
on low-energy processes violating baryon and lepton numbers.

3 Phenomenology: Neutron-Antineutron physics and LHC

An operator like (9) generates neutron-antineutron transitions, violating baryon number
with $\Delta B = 2$, as shown in Fig.1 and discussed in [1]. The scale $\mathcal{M}_{nn}^5 = m_{\tilde{g}}^2 \mathcal{M}_0^2 \mathcal{M}_{\tilde{H}}$
in $(udd)^2/\mathcal{M}_{nn}^5$ is a combination of the gaugino (gluino or zino) mass $m_{\tilde{g}}$, of the mixing
mass term $\mathcal{M}_0$ for the vector-like pair and the Higgsino mass $M_{\tilde{H}}$. In order to satisfy
Figure 2: Diagram inducing neutron-antineutron transitions through vector-like pair of scalars and an Higgsino. The scalars of the superfields $D' - C$ are mixing through a loop of their fermionic superpartners (the white blob represent the non-perturbative mass term induced by exotic instantons) and a gaugino.

the present experimental bound $M_{n\bar{n}} > 300$ TeV, we can consider different scenarios. We focus on some of these in the following:

i) Higgsini, Gaugini and vector-like pairs at the same mass scale $300 - 1000$ TeV, in order to trivially satisfy the bound;

ii) Susy breaking at the TeV scale, with $M_{\tilde{g}} \simeq M_{\tilde{H}} \simeq 1$ TeV, and $M_0 \sim 10^{15+16}$ GeV;

iii) Heavy Higgsini and gaugini: $M_{\tilde{g}} \simeq M_{\tilde{H}} \simeq M_{SUSY} \simeq 10^4$ TeV, $M_0 \simeq 1$ TeV.

Another diagram generating $n - \bar{n}$ transitions is depicted in Fig.2, the analysis of the parameter space is roughly the same as for the first case.

These diagrams respect R-parity at all the vertices, except for the non-perturbative mixing term of the vector-like pair. In fact the super-potential has $R(W) = -1$ as usual, and one can consistently assign R-charges to $C$ and $D'$, so that their tri-linear Yukawa terms be invariant. Yet their mass term necessarily violates R-parity. Omitting the coupling constants one schematically has

$$L_Y = \psi_C \tilde{q}^+ q^+ + \phi_{D'} q^+ \psi_{H_d} + \phi_C q^+ q^+ + \psi_{D'} q^+ \phi_{H_d} + M_0 \psi_C \psi_{D'}$$

where $\pm$ indicates the R-parity, $\phi_{C,D'}$ and $\psi_{C,D'}$ are the scalars and the fermions respectively in the superfields $C, D'$, $q, \tilde{q}$ are quarks and squarks, $\phi_{H_u,d}$ are Higgs bosons, $\psi_{H_u,d}$ are the two Higgsini. Note how R-parity is violated only by the last non-perturbative term with mixing mass parameter $M_0$ not directly connected to the Dirac mass term for $D'$, emerging from its ‘standard’ coupling to the Higgs.

More precisely, $M_0$ is replaced by the mass parameter of the lightest mass eigenstate, be it a fermion $\psi_{D',C}$ as in Fig.1, or a scalar $\phi_{D',C}$ as in Fig.2. The scalars $\phi_{D',C}$

\footnote{In \cite{1}, we have made the tacit and not fully justified assumption that the gaugino mass were $m_{\tilde{g}} \simeq M_0$. Here, we relax this assumption.}
have in general a non-diagonal mass matrix \[ M_2 \] of the form

\[
M_2 = \begin{pmatrix}
  m_{\phi_{D'}}^2 & 0 & \delta \mu^2 & 0 \\
  0 & m_{\phi_{D'}}^2 & 0 & -\delta \mu^2 \\
  \delta \mu^2 & 0 & m_{\phi_C}^2 & 0 \\
  0 & -\delta \mu^2 & 0 & m_{\phi_C}^2
\end{pmatrix}
\] (11)

written in the basis \((\phi_{1D}', \phi_{2D}', \phi_{1C}, \phi_{2C})\), with \(\phi_{D',C} = \phi_{D',C}^0 + i \phi_{D',C}^1\) (assuming \(\delta \mu = \delta \mu^*\)), and with

\[
L_m = m_{\phi_{D'}}^2 \phi_{D'}^\dagger \phi_{D'} + m_{\phi_C}^2 \phi_C^\dagger \phi_C + h.c
\] (12)

and \(\delta \mu^2 \sim m_\tilde{g} M_0\) as in Fig.2.

The mass eigenvalues of (11) are

\[
\lambda_\pm^2 = \frac{1}{2} \left( m_{\phi_{D'}}^2 + m_{\phi_C}^2 \pm \sqrt{4 \delta \mu^4 + (m_{\phi_{D'}}^2 - m_{\phi_C}^2)^2} \right)
\] (13)

both doubly degenerate, as manifest in (11). Note that, in the case of \(m_{\phi_{D'}} = m_{\phi_C} = 0\) and \(\delta \mu \neq 0\), one of the mass eigenvalue is negative, i.e. leading to a condensate, breaking \(SU(3)_c\).

On the other hand, we would like to note that Dirac mass terms for fermions \(\psi_{D'}\) and \(\psi_C\) are not present at all. For instance, \(\psi_{D'}\) is like a 4th right-handed down quark without a Left-Handed counterpart. As a result \(m_\pm = \pm M_0\), where the sign, in fact any phase, can be absorbed into a redefinition of the phases of the fermionic fields.

We can distinguish two branches for LHC and FCNCs phenomenology: i) Normal Susy hierarchy; ii) Inverted Susy hierarchy.

In Normal Susy hierarchy, scalars \(\phi_{D',C}\) have the highest mass eigenstate \(\lambda_- << |m_-|\), i.e scalars have lower masses with respect to their supersymmetric fermionic partners. This case is an ordinary hierarchy between fields and their supersymmetric partners. In this case, the relevant contribution for Neutron-Antineutron oscillations is the one in Fig.2. In principle, \(M_0 m_\tilde{g}\) has to be substituted, in the parameters estimations for \(n - \bar{n}\) oscillations shown above, with the highest mass \(\lambda_\pm^2\). For \(m_{\phi_C}^2 >> m_{\phi_{D'}}^2 \approx m_\tilde{g} M_0\), we obtain \(\lambda_- \approx M_0\), and dangerous FCNC’s can be suppressed if \(m_{\phi_C}^2 >> m_{\phi_{D'}}^2\) [2]. In particular, assuming \(m_{\phi_C}^2 \approx 10^6 m_{\phi_{D'}}^2\) and \(M_0^2 \approx m_{\phi_{D'}}^2\), we obtain, from (13): \(\lambda_+^2 \approx m_{\phi_{D'}}^2\) and \(\lambda_-^2 \approx m_{\phi_C}^2\), with mixing angles \(\theta_{13} = \theta_{24} \sim 10^{-6}\). So, mixings between \(X\) and \(Y\) are strongly suppressed in this case, but may be enough for neutron-antineutron transitions: a prefactor of \(10^{-12}\) in a \(n - \bar{n}\) scale \((M_0^{4\mu})^{1/5}\) has to be included. This drastically changes the constraints on the other parameters: for \(M_0 = 1 - 10\) TeV, a light \(\psi\) of \(\mu = 1 \div 100\) GeV would be enough! The phenomenology
of (i) is discussed in [2]. In [2], a toy-model was shown in which the so called $\mathcal{X}, \mathcal{Y}$ are nothing but $\phi_{D',C}$ respectively. There are some subtle differences not allowing a perfect identification $\mathcal{X} = \phi_{D'}$ and $\mathcal{Y} = \phi_C$. For example, in the main interactions terms, like $\mathcal{Y} u_R^R d_R^R$ rather than $\phi_C u_L u_R$, or $\mathcal{X} d_R^R \psi$ rather than $\phi_C d_L \tilde{H}$; with $\psi$ a sterile Majorana fermion with zero hypercharge rather than an Higgsino. This leads to some subtle differences in hypercharge assignments (reversed in the vector-like pair) and Baryonic number assignment (opposite sign in both), compatible with gauge symmetries. Even so, the phenomenology is very similar to the one discussed in [2], in so far as neutron-antineutron oscillations, LHC signatures, FNCN’s, and Post-Sphaleron Baryogenesis are concerned. For instance, the lightest mass eigenstate scalars can have $\lambda_- \simeq 1 \, \text{TeV}$, with possible channels at LHC. In particular, $pp \rightarrow jj E_T$ is previewed, avoiding stronger constraints from FCNC’s processes. Our models also predict $pp \rightarrow 4j$ (direct bound of 1.2 TeV) or $pp \rightarrow t\bar{t}jj$ (direct bound of 900 GeV), but FCNC bounds are stronger than LHC ones, in these cases.

In the Inverted Susy Hierarchy, we consider the opposite scenario in which $M_0 << \lambda_-$, i.e. susy fermions $\psi_{D',C}$ are lighter than scalars $\phi_{D',C}$. We also would like to note that, in principle, a scenario in which the fermions $\psi_{D',C}$ can be at lower masses with respect to their scalar partners $\phi_{D',C}$ is perfectly possible: the second ones can get extra contributions from (non-perturbative) non-supersymmetric closed-string fluxes (NS-NS or R-R), not contributing to fermionic masses. In this case, direct detection of $\psi_C - \psi_{D'}$ at LHC would be possible. For instance, it is possible to produce these in different processes, having peculiar decay channels like $\psi_C \rightarrow q\bar{q}$. We would like to note that in our case one can also generate perturbative Yukawa terms of $\psi_{D'}$ with the bottom quark, leading to a decay channel $\psi_{D'} \rightarrow Hb$. Moreover, an electroweak mixing with the top quark is also possible, that would lead to $\psi_{D'} \rightarrow Wt$. These could be interesting for LHC. The limits on these rare processes are shown in ATLAS EXPERIMENT Public Results in the section devoted to Exotics [43]. The limits on the mass of an additional vector-like pair are of order $500 - 850 \, \text{GeV}$.

So, thanks to the non-perturbative R-parity breaking mixing mass term $M_0 \epsilon_{ijk} C^{ij} D_k$, the phenomenology of our model is different with respect to the one of other models with vector-like pairs. Otherwise, a low mass higgsino and consequently a low mass LSP neutralino, detectable at LHC, would be possible if the mass of the vector-like pair

---

6See for example [37, 38], for discussions about soft susy breaking terms generated by fluxes in MSSM’s in (unoriented) open string theories.
\( \mathcal{M}_0 \) were around \( 10^{12-15} \) TeV. This last scenario can be compatible with susy breaking scale around some TeV’s.

3.1 Dangerous operators: no proton decay without right-handed Majorana neutrini

Let us consider a complete and extended super-potential consisting of the R-parity preserving Yukawa terms of the MSSM (2), the new perturbative Yukawa terms of \( C \) and \( D \), the non-perturbative mixing mass term of the vector-like pair, and the interaction terms of an extra Right-Handed neutrino \( N \), with Majorana mass term and perturbative Yukawa term:

\[
\mathcal{W} = y_u H_u Q U^c + y_d H_d Q D^c + y_l H_d L E^c + y_N H_u L N^c + \mu H_u H_d
\]

\[
+ \frac{1}{2} m_N^2 N^2 + h_C C Q Q + h_D H_d Q D^c + \mathcal{M}_0 D' C
\]

In order to integrate out the massive super-fields, \( N, H_u, H_d, C, D' \), we have to evaluate the field-dependent mass matrix \( M_{FJ}(\Phi) \), where \( \Phi \) collectively denotes the light super-fields, and invert it

\[
\mathcal{W}_{eff}(\Phi) = \frac{1}{2} F^I(M_F)^{-1}J(\Phi) F^J
\]

where \( F_I = \{ F_N, F_{H_u}, F_{H_d}, F_C, F_{D'} \} \) indicate the ‘massive’ F-terms. The relevant mass matrix is the inverse of

\[
M_F = \begin{pmatrix}
    m_N & L & 0 & 0 & 0 \\
    L & 0 & \mu & 0 & 0 \\
    0 & \mu & 0 & 0 & Q \\
    0 & 0 & 0 & 0 & \mathcal{M}_0 \\
    0 & 0 & Q & \mathcal{M}_0 & 0
\end{pmatrix}
\]

(16)

Due to the non-trivial dependence on the superfields \( Q \) and \( L \), direct inversion inversion of (16) becomes laborious but straight-forward with the result

\[
(M_F)^{-1} = \begin{pmatrix}
    \frac{1}{m_N} & 0 & -\frac{L}{m_N \mu^2} & \frac{L Q}{m_N \mathcal{M}_0 \mu} & 0 \\
    0 & \frac{1}{\mu} & \frac{1}{m_N \mu^2} & \frac{L Q}{m_N \mathcal{M}_0 \mu^2} & 0 \\
    -\frac{L}{m_N \mu^2} & \frac{1}{\mu} & \frac{1}{m_N \mu^2} & \frac{L Q}{m_N \mathcal{M}_0 \mu^2} & 0 \\
    \frac{m_N \mathcal{M}_0 \mu}{L Q} & \frac{m_N \mathcal{M}_0 \mu}{L Q} & \frac{m_N \mathcal{M}_0 \mu}{L Q} & \frac{1}{m_N \mathcal{M}_0 \mu^2} & 0 \\
    0 & 0 & 0 & \frac{1}{m_N \mathcal{M}_0 \mu^2} & \frac{1}{\mathcal{M}_0}
\end{pmatrix}
\]

(17)

\[^7\] For simplicity, couplings and flavour structure are understood since they are not relevant in the subsequent discussion.
A perturbative approach, alternative but equivalent to the exact inversion (47) is reported in Appendix.

On-shell the F-terms yield

$$F_N = 0$$  
$$F_{H_u} = QU^c$$  
$$F = QD^c + LE^c$$  
$$F_C = QQ$$  
$$F_{D'} = 0$$

Replacing their expressions into $W_{\text{eff}}(\Phi)$, we obtain the following extra and potentially dangerous operators (relevant coupling constants are omitted for simplicity):

$$W_{1\text{th}} + W_{2\text{th}} = \frac{1}{\mu M_0} QQQU^c + \frac{L^2}{\mu^2 m_N} (QD^c + LE^c)^2$$

$$W_{3\text{th}} = \frac{L^2 Q}{m_N \mu^2 M_0} (QQ)(QU^c + LE^c)$$

We report also the only one remaining at the 4th order:

$$W_{4\text{th}} = \epsilon_{ijk} \epsilon_{i'j'k'} (Q^i Q^j) \frac{Q^k L L Q^{j'}}{\mu^2 m_N M_0^2} (Q^{j'} Q^{k'})$$

In the limit of $m_N \rightarrow \infty$, all the dangerous operators are automatically suppressed. In fact, only $QQQU^c/\mu M_0$ remains, but this cannot lead to proton decay, as discussed in [1]. Also combining such operator with other perturbative ones, one can check that all the resulting effective operators are innocuous: there is no operator leading to a final state without at least one susy partner (so, no available phase space for proton decay), without violation of any fundamental symmetry like charge, spin or fermion number.

In fact our models may be tuned not to violate Lepton number, by setting $m_N = 0$, by turning on fluxes or other means that prevent any E2-brane instanton that may generate $m_N$ [44]. The price to pay is that a type I see-saw mechanism for the neutrino is not allowed: we cannot generate a Majorana mass without fast proton decay. So, such processes as neutrino-less double-$\beta$ decay would provide evidence against these class of models. Of course, a Dirac mass for the neutrino $\mathcal{W} = H^a_\alpha L_\alpha N \rightarrow L_Y = \phi_H^a \ell^a \nu_0$ is allowed if R-H sterile neutrini are present.
3.2 Flavour changing neutral currents

Extra contributions to FCNC’s may appear in our models, mediated by $\phi_C$, in normal susy hierarchy, as cited above. But these can be sufficiently suppressed, compatible with $n - \bar{n}$ limits.

Other possible contributions, directly connected to $n - \bar{n}$ transitions, are strongly suppressed in our model, as discussed in [11] (See Fig. 11-12 in [1]: note that extra quarks-squarks conversions are understood that would further suppress the diagrams by the mass of the gaugini). In particular, extra contributions to neutral meson-antimeson oscillations like $\pi^0 - \bar{\pi}^0$, $K^0 - \bar{K}^0$, $D^0 - \bar{D}^0$ are strongly suppressed, approximately by a power $\mathcal{M}_0^{-4}M_{\tilde{H}}^{-2}M_{\text{SUSY}}^{-2}$. This depends roughly on $M_{\text{SUSY}}$, in particular it depends on the diagram under consideration whether gaugini or squarks give extra suppressions. Also in meson decays into two mesons, the suppressions are of the same order: $\mathcal{M}_0^{-4}M_{\tilde{H}}^{-4}M_{\text{SUSY}}^{-2}$.

4 Standard Model like quivers generating a Majorana Neutron

Our aim, in this section, is to identify possible (un)oriented quiver field theories for the models introduced above, thus generating a neutron Majorana mass. As discussed above the ingredients are un-oriented strings stretched between D6-branes stacks. We will also need $E2$-branes, wrapping some 3-cycles in $CY_3$. Thanks to the local CY condition, the resulting theory preserves $N = 1$ supersymmetry.

4.1 What is a quiver field theory?

In general, a quiver, a collection of arrows, represents a gauge theory, with its matter (super)field content. In a quiver, gauge groups are represented by nodes, and the fields are represented as (oriented) lines between the nodes. Adjoint representations start and end on the same node, bi-fundamental representations $(\mathbf{N}, \mathbf{\bar{M}})$ or $(\mathbf{\bar{N}}, \mathbf{M})$ connect two different nodes. A common example is $U(N) \times U(M)$ in the oriented case. In the un-oriented case $SO(N)$ and $Sp(2N)$ arise from nodes invariant under a mirror-like involution $\Omega$, associated to the presence of $\Omega$-planes. In this case, (anti)symmetric representations $\mathbf{N}(\mathbf{N} \pm \mathbf{1})/2$ or $\mathbf{\bar{N}}(\mathbf{\bar{N}} \pm \mathbf{1})/2$ as well as $(\mathbf{N}, \mathbf{M})$ or $(\mathbf{\bar{N}}, \mathbf{\bar{M}})$ correspond to strings going through the mirror. In the non-supersymmetric case, a quiver distinguishes scalars and fermions as different kinds of arrows between nodes. On the other
hand, in a supersymmetric case, a quiver becomes more economic: arrows are superfields, representing both scalars and fermions, and nodes include gaugini as well as gauge fields.\footnote{For extended SUSY models with $\mathcal{N} = 2, 4$ one can either use an $\mathcal{N} = 1$ notation, with arrows representing chiral multiplets and nodes representing vector multiplets, or an $\mathcal{N} = 2$ notation, with unoriented lines representing hypermultiplets and nodes representing vector multiplets.} The number of arrows on a line correspond to the number of generations or replicas of the same (super)field. A quiver encodes also the possible interactions: closed paths (triangles, quadrangles etc) that respect the orientation of the arrows, represent possible gauge-invariant super-potential or interaction terms. An effective low energy description of the dynamics of D3-branes at Calabi-Yau singularities can be represented as a quiver field theory. In this case, standard D-brane stacks are nodes, lines connecting the nodes are (un)oriented open strings stretching between two D-brane stacks, Euclidean D-branes (instantons) are represented by extra or unoccupied nodes, ‘dashed’ oriented lines connecting these with the original nodes represent modulini. In the quiver notation, interactions between modulini and standard fields also correspond to closed polygons (usually triangles) of lines and dashed lines.

A large class of $\mathcal{N} = 1$ superconformal QFTs can arise form D3-branes transverse to CY singularities. Near the horizon, the geometry is $\text{AdS}_5 \times X$, where $X$ is an Einstein-Sasaki space, base of a Calabi-Yau cone\cite{45,46,47,48}. Quivers can be complicated, by the inclusion of $\Omega$-planes and flavour branes. These generically break superconformal invariance\cite{49}. Including such elements seems necessary for a realistic particle physics model building\cite{49,50,51,52,53}. The brane system is located at at the fixed point of the orientifold involution, and the low energy dynamics is described, locally, by an un-oriented quiver theory, with local tadpole cancellation for its consistency at the quantum level, \textit{i.e.} absence of chiral gauge and gravitational anomalies. An interesting example, studied in\cite{54}, is the case of $\mathbb{C}^3/\mathbb{Z}_n$ singularities, in the presence of non-compact D7-branes, fractional D3-branes, and $\Omega$-planes.

4.2 Explicit examples

An example of a simple quiver theory generating a Majorana mass for the neutron is shown in Fig. 3. This consists in: one stack of three D6-branes producing the $U(3)$ gauge group, that includes the $SU(3)$ color group and an extra $U(1)$; two stacks of single D6-branes producing two $U(1)$ gauge groups, an $\Omega$-plane identifying the D-brane stacks with their images; one stack of two D6-branes, on the $\Omega$-plane, forming an $Sp(2)$ gauge
group, producing the $SU(2)_L$ weak group. As usual in quiver convention, the gauge groups (D-branes stacks) are identified with black circles (with a label 3 for $U(3)$, a label 2 for $Sp(2)$ and labels 1, 1' for $U(1), U(1)'$); the fields, living in the bi-fundamental representation of two gauge groups (strings stretched between two stacks of D-branes) are represented as arrows linking the two groups involved. All the Standard Model super-fields are recovered in the present construction. Another check for consistency is to verify that the standard Yukawa super-potential terms are recovered. In this notation, these corresponds to closed circuits (oriented triangles) with sides the super-fields coupled via the Yukawa terms. For example, it is straightforward to verify that $Q, D, H_d$ form an oriented triangle respecting the orientation of the arrows. So, we recover the standard Yukawa terms $H_3^α Q_i D_i^c$, $H_u^α L_α E^c$, $H_u^α Q_i U_i^c$ and their flavour structure. The insertion of the 4th generation of D-quarks involves another arrow for the consistency of the quiver. This arrow is compensated exactly by $C$, coming from the line between the two images of $U(3)$'s. The balance of the arrows is fundamental to have an anomaly-free model and tadpole cancellation\footnote{It may look suspicious that $Ω$ acts symmetrical on the D-brane stack producing $Sp(2)$ and anti-symmetrical on the two images of $U(3)$. In the end this is the only choice compatible with the absence of irreducible anomalies. A symmetric irrep (6) of $SU(3)$ would lead to an inconsistency.}. On the other hand, also the new perturbative Yukawa terms necessary for neutron-antineutron transition are generated in our model. $Q_i$ in the left side and $\hat{Q}_j$ in the right side of Fig.3 are closing a circuit with the new exotic field $C^{ij}$ living at the intersection between $U(3)$ and $\hat{U}(3)$ (with the hat, we denote the images in the right side of the $Ω$-plane in Fig. 1). As a consequence, a perturbative Yukawa term $C^{ij} Q_i \hat{Q}_j$ is generated. On the other hand, $D^c Q H_d$ is generated exactly as the corresponding standard one $D^c Q H_d$.

Finally, the relevant exotic $O(1)$ instanton $E2$, generating the non-perturbative mixing between $D'$ and $C$, is also represented in Fig. 3. As dashed lines we also denote the modulini living at the intersections between $E2$ and the $U(3)$ and $U'(1)$ stacks of $D6$-branes. The hypercharge in this model is the combination of 3 charges coming from $U(1)_3, U(1), U'(1)$:

$$Y(Q) = aq_3 + bq_1 + cq_1'$$

We can fix the coefficients from the conditions that arise in order to recover the standard hypercharges:

$$Y(Q) = \frac{1}{3} = -a$$

(27)
Figure 3: (Susy) Standard Model quiver generating a Majorana mass for the neutron.

\[
Y(U^c) = -\frac{4}{3} = a - b \tag{28}
\]
\[
Y(H_u) = 1 = b \tag{29}
\]
\[
Y(D^c) = Y(D^{c'}) = \frac{2}{3} = a - c \tag{30}
\]
\[
Y(L) = Y(H_d) = -1 = c \tag{31}
\]
\[
Y(E^c) = 2 = -2c \tag{32}
\]
\[
Y(C) = -\frac{2}{3} = 2a \tag{33}
\]

leading to the result

\[
a = \frac{1}{3}, \quad b = -1, \quad c = 1 \rightarrow Y = \frac{1}{3}q_3 - q_1 + q_{1'} \tag{34}
\]

For the quiver in Fig. 3, it is possible to generate a mixing mass term for the Higgses like \(\mu H_u H_d\) through exotic instantons, too. In fact, we can put another exotic instanton \(E2'\) connected to \(U(2) - U'(1)\) and thus \(H_d\) and and to \(U(2) - U(1)\) and thus \(H_u\). This introduces effective interactions between \(H_u, H_d\) and the modulini living on the intersections, producing \(W_H = M_S e^{-S_{E2'} H_u H_d}\).

We should remark that the quiver represented in Fig. 3 could generate extra R-parity breaking terms \(\lambda' L Q D^c\) in \([3]\) or \(\lambda'' L Q D^{c'}\), leading to a mixing of quarks and leptons. These dangerous operators can be tuned to zero, since not all closed triangles or more generally polygons necessarily correspond to interaction terms.
Figure 4: Another (Susy) Standard Model’s quiver generating a Majorana mass for the neutron.

As an alternative, we can consider the quiver in Fig. 4, consistent with the hypercharges:

\[
Y(Q) = \frac{1}{3} = -a \tag{35}
\]

\[
Y(U^c) = -\frac{4}{3} = a - b \tag{36}
\]

\[
Y(H_u) = 1 = -c \tag{37}
\]

\[
Y(D^c) = Y(D^{c\prime}) = \frac{2}{3} = a - c \tag{38}
\]

\[
Y(H_d) = -1 = c \tag{39}
\]

\[
Y(L) = -1 = -b \tag{40}
\]

\[
Y(E^c) = 2 = -2c \tag{41}
\]

\[
Y(C) = -\frac{2}{3} = 2a \tag{42}
\]

leading to the result

\[
a = -\frac{1}{3}, \ b = 1, \ c = -1 \rightarrow Y = -\frac{1}{3}q_3 + q_1 - q_1' \tag{43}
\]

We get all the standard Yukawa terms in this case, too. We may also have the R-parity breaking term $\mu_a L_a H_u$ with $\Delta L = 1$. We will assume that such a term is absent at the perturbative level and is not generated non-perturbatively. Since other R-parity violating terms in (3) are automatically disallowed at the perturbative level, our model
is R-parity invariant to start with. Taking into account the non-perturbative term $QQQH$ indirectly generated through exotic intantons, and the $\mu$-term $\mu H_u H_d$ possibly generated by exotic instantons, too, similarly to the other one discussed above.

Other R-parity breaking contributions may arise from higher order vertices, corresponding to closed polygons with more than 3 sides, not present in the other case:

$$\mathcal{W}_{V>3} = y_{LH_d D^c Q} \frac{1}{M_S} LH_d D^c Q + y_{U^c Q^c H_u D^c} \frac{1}{M_S} U^c QH_d D^c$$

(44)

Clearly these operators are dangerous. For instance, combining $\mathcal{W}_{V>3}$ with the non-perturbative operator (9) with (44), yields

$$\mathcal{W}'_{\text{eff}} = \frac{1}{M_S M_0 \mu} QQQQU^c D^c + \frac{1}{M_S M_0 \mu} QQQQLQ D^c$$

(45)

The first term can lead to neutron-antineutron transitions and di-nucleon decays $pp \rightarrow \pi^+\pi^+, K^+K^+$, the second term to proton decay $p \rightarrow \pi^0 e^+$. The ratio of the proton life-time to the neutron-antineutron transition time is

$$\tau_{n\bar{n}} \simeq \frac{M_0}{M_S} \tau_{p-\text{decay}} \simeq e^{-S_{E2}} \tau_{p-\text{decay}}$$

(46)

This hierarchy is much higher than the present limit on $D' - C$ vector-like pairs at colliders. In fact, with $\tau_{p-\text{decay}} \approx 10^{34\div35} \text{yr}$ and $\tau_{n\bar{n}} \approx 3 \text{yr}$, $M_0 \approx 10^{-35} M_S << M_0|_{\text{exp}}$, where $M_0|_{\text{exp}} \approx 0.5 \div 1 \text{TeV}$ is the direct bound from colliders discussed above. For di-nucleon decay the situation is better, but also in this case the required tuning is extremely delicate, considering that $\tau_{d\bar{d}-\text{decay}} \approx 10^{32} \text{yr}$ [55]. So, we conclude that a tuning of the coupling constants $y_{LH_d D^c Q}, y_{U^c Q^c H_u D^c}$ to zero would be necessary in this case.

4.3 Extended quivers and CY singularities

The quivers, proposed in Fig.3-4, have different numbers of arrows entering/exiting each node. As a consequence, these do not seem to be systems of D-branes transverse to a local Calabi-Yau singularity. On the other hand, Fig. 3-4 can be viewed as subsystems of larger quivers, possibly with flavor branes restoring a perfect balance of entering/exiting arrows. In this way, we can see Fig. 3-4 as projections of systems on a local orbifold or CY singularity, in the presence of $\Omega$-planes and Flavor Branes. In general, configurations, with flavor branes and orientifold planes $\Omega$, can provide examples of realistic models for particle physics, containing SM. In these, the super-conformal $\mathcal{N} = 4$ theory is broken to an $\mathcal{N} = 1$ theory. The low-energy dynamics is governed by
a local unoriented quiver theory, in which consistency at the quantum level depends on local tadpole cancellation. For some examples of unoriented quivers with Flavor, it is possible to show explicitly relations between tadpoles and anomalies in presence of flavor branes [56, 57, 58, 54].

Among the variety of possibilities, we propose a simple extension of the quiver in Fig. 4, shown in Fig. 5. We would like to stress that this is only one example among different possible quivers.

5 Kähler potential, D-terms and perturbative corrections

So far we have focussed on the super-potential interactions, both perturbative and non-perturbative ones. We have argued that barring explicit R-parity violating terms in the Lagrangian, R-parity is broken dynamically by non-perturbative exotic instanton effects. This implies that it is preserved in perturbation theory, at least in so far as we keep supersymmetry unbroken. Since supersymmetry has to be broken by ‘soft terms’ one may be worried about proton decay and other undesired effects. However, even before addressing the issues related to soft SUSY breaking, one may wonder whether D-terms and corrections to the Kähler potential may affect our analysis significantly. Although little is known about quantum corrections to the Kahler potential and D-terms in the intersecting D-brane models, some progress has been made in [59, 60, 61, 62].
The main idea is to use in a sense the locally supersymmetric version of the exact Novikov-Shifman-Vainstein-Zakharov $\beta$ function in order to derive an exact (perturbative) relation between corrections to $K(\Phi, \Phi^\dagger)$ and thus anomalous dimensions $\gamma$, related to wave-function renormalisation $Z_\Phi$, and running of $g_{YM}$ and thus $\beta$ function. Except for theories or sectors with at least $N = 2$ susy, whereby the Kähler potential for the vector multiplet is directly related to the holomorphic pre-potential and thus to the gauge couplings i.e. the gauge kinetic function and can be computed, when susy is minimal i.e. $N = 1$, the relation is much looser. In principle $K$ and the D-terms in general, can get any sort of perturbative corrections. However these are to be compatible with the ‘classical’ symmetries, which include R-parity, baryon number $B$ and Lepton number $L$. It is also known that standard ‘gauge’ instantons can only generate terms violating ‘anomalous’ symmetries, while ‘exotic’ instanton can violate non-anomalous ones, such as $B - L$ in the (MS)SM. Depending on the number of fermionic zero-modes both gauge and exotic instantons may correct the gauge kinetic function(s), D-terms and the Kahler potential. It is rather reasonable to assume that such non-perturbative corrections be absent or very small in the quiver models in our classes, even when the string scale is close to – but smaller than – the Planck scale so much so that the full super-gravity structure should be taken into account.

In summary, the only ‘seed’ of R-parity breaking and Baryon (and/or Lepton) number violation seems to be the super-potential.

When supersymmetry gets broken, say in a hidden (strongly coupled) sector and then communicated to the visible sector, the situation gets more intricate. The structure of the low-energy Lagrangian, though constrained by the original supersymmetry, allows for dangerous mixings. In the quiver models we consider, proton stability, as previously discussed, largely relies on Lepton number conservation or on the fact that the final states should contain at least one susy partner. In Pati-Salam like models, it’s built in via the selection rule $\Delta B = 2$.

6 Conclusions

We have produced two examples of consistent quiver fields theories, indirectly generating a Majorana mass term for the neutron by means of exotic instantons. These are free of local tadpoles and thus irreducible anomalies.

The phenomenology exposed by this class of models is interesting both for neutron-
antineutron physics and LHC or other colliders, where a new vector-like pair could be detected. On the other hand, the models we suggest can be tuned to suppress FCNC’s. However, in order to prevent fast proton decay, Lepton number is not to be violated. An alternative is to consider $SO(10)$ GUT models or Pati-Salam like models in string theory that can lead to $\Delta B = 2$ processes but no $\Delta B = 1$ [63, 64, 65, 66, 67, 68]. Although perturbative un-oriented strings do not admit spinor representations of orthogonal groups, P-S like models are easy to embed in this context [70]. In $SO(10)$ neutrino Majorana masses are generated by Higgses in the $126$ that involve $(10,1,1) + (10^*,1,3)$ of the PS group $SU(4) \times SU(2)_L \times SU(2)_R$. These cannot appear either in perturbative open string settings. Yet combining $(10,1,1) + (10^*,1,1)$ with $(1,3,1) + (1,1,3)$ that are allowed one can achieve the goal of first breaking $SU(4)$, then $SU(2)_R$ and finally $SU(2)_L \times U(1)_Y$ to $U(1)_{e-m}$ and get Majorana neutrini and neutrons with a stable proton. We plan to discuss this class of models in a forthcoming paper.

In principle, it is possible to construct various quivers with flavor branes, generating other fascinating effects for phenomenology. A complete classification could reserve us some surprises. It remains to search Calabi-Yau compactifications leading to global embeddings of models of this kind.

To conclude, the class of models considered represents an intriguing example of a phenomenological effective model of string theory beyond the standard model, that could be tested by the next generation of experiments.

Appendix: Integrating out massive super-fields

We find it more intuitive to apply a perturbative approach that we report in the following for pedagogical purposes.
Setting \( M_F = M_F^0 + \mathcal{E} \), with

\[
M_F^0 = \begin{pmatrix}
m_n & 0 & 0 & 0 & 0 \\
0 & 0 & \mu & 0 & 0 \\
0 & \mu & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & \mathcal{M}_0 \\
0 & 0 & 0 & \mathcal{M}_0 & 0
\end{pmatrix}
\]  

(47)

\[
\mathcal{E} = \begin{pmatrix}
0 & L & 0 & 0 & 0 \\
L & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & Q \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & Q & 0 & 0
\end{pmatrix}
\]  

(48)

the inverse mass matrix can be calculated as a perturbative series

\[
M_F^{-1} = (M_F^0)^{-1} - (M_F^0)^{-1} \mathcal{E} (M_F^0)^{-1} + (M_F^0)^{-1} \mathcal{E} (M_F^0)^{-1} \mathcal{E} (M_F^0)^{-1} + \ldots
\]

(49)

In our case, combining (48) and the inverse of (47) one gets the first perturbation

\[
(M_F^0)^{-1} \mathcal{E} (M_F^0)^{-1} = \begin{pmatrix}
0 & 0 & \frac{L}{m_N \mu} & 0 & 0 \\
0 & 0 & 0 & 0 & \frac{Q}{\mu \mathcal{M}_0} \\
0 & \frac{L}{m_N \mu} & 0 & 0 & 0 \\
0 & \frac{Q}{\mu \mathcal{M}_0} & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix}
\]

(50)

then the second perturbation is

\[
(M_F^0)^{-1} \mathcal{E} (M_F^0)^{-1} \mathcal{E} (M_F^0)^{-1} = \begin{pmatrix}
0 & 0 & 0 & \frac{L Q}{m_N \mu \mathcal{M}_0} & 0 \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & \frac{L^2}{m_N \mu^2} & 0 & 0 \\
0 & \frac{Q L}{m_N \mu \mathcal{M}_0} & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix}
\]

(51)

the third perturbation is

\[
(M_F^0)^{-1} \mathcal{E} (M_F^0)^{-1} \mathcal{E} (M_F^0)^{-1} \mathcal{E} (M_F^0)^{-1} = \begin{pmatrix}
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & \frac{L^2 Q}{m_N \mu^2 \mathcal{M}_0} & 0 & 0 \\
0 & \frac{L^2 Q}{m_N \mu^2 \mathcal{M}_0} & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix}
\]

(52)

At the fourth order, we recover the exact result cited above in the paper.
