Mining online social networks with Python to study urban mobility

Antònia Tugores†, Pere Colet†

Abstract—On-line social networks have grown quickly over the last few years and nowadays many people use them frequently. Furthermore the emergence of smartphones allows to access these networks any time from any physical location. Among the social networks, Twitter offers a particularly large set of data publicly available. Here we discuss the procedure to mine this data and store it in distributed databases using Python scripts. We also illustrate how geolocated tweets can be used to study the mobility of people in urban areas.

Index Terms—big data, noSQL, data acquisition, online social networks

1 INTRODUCTION

Although online social networks appeared already in the later nineties, their growth has taken place mainly in the last decade, in parallel to that of devices providing mobile internet connections. Out of these online social networks, some of them consider the data to be private while others emphasize in distributing the information publicly. Out of the last ones, Twitter is, by far, the larger. Tweets, intended as a compact way to share an opinion to the world, also contain several kinds of information on the user and way it has been sent. In particular, it may include the geolocation at the time it is send. This information can be used to study the mobility behaviour of people in urban areas, including attitudes and lifestyle, which are particularly important for e.g. developing demand management concepts for influencing mobility decisions.

The objective of this paper is to discuss efficient ways to retrieve and store large amounts of data from social networks, such as Twitter. Since the fraction of tweets that can be downloaded from Twitter is limited, besides a random sample, we select the users which are located in the cities under study. We use Python scripts to interact with Twitter API, in particular with Tweepy, and to decide which are the users to be selected. To improve efficiency data is stored in a distributed way using MongoDB noSQL data base. Finally we perform searches on the database using the Python MongoDB driver to extract the relevant information to study human mobility patterns. The paper is organized as follows, we first provide a brief discussion on SQL and noSQL databases. The next section explains how data is acquired and how users are selected. Then we compare the performance of a SQL database with an distributed noSQL one. Finally, some preliminary mobility results are shown and we give some concluding remarks.

2 DATA STORAGE

Storage of data in plain files is not practical when dealing with thousands of millions of tweets, even if each document is as small as a tweet. It is much more convenient to store them in a database, which also allows for multi user-access to the information. High availability, performance, scalability and recoverability, together with good drivers, easy administration and preferably open source are some of the desirable characteristics of a database to store large amounts of data for a long period of time.

2.1 SQL vs noSQL

Traditional databases rely on collections of tables with data records, which are formally described and organized according to a relational model. This is known as Relational Database Management System, RMDBS) as introduced by E.F. Codd [Codd]. Relational databases are widely adopted and tested. As a consequence, Atomicity, Consistency, Isolation and Durability (also known as ACID) is supported as well as crash recovery, and master-slave consistency, which explains why they have been actively used in production since the seventies. There are different tools to access relational databases but, by far Structured Query Language (SQL) is the most common. Therefore the term SQL is in many instances used as synonym to relational database. On a relational database, data can not be inserted in an arbitrary way. One has first to parse the data prior to insertion, which for fast data archival may constitute a bottleneck. Typically a SQL database is stored in a pair of master-slave servers. Since insertion and queries are performed on the same computer, performance depends on the hardware of this computer and scalability involves improving the existing hardware.

On the contrary, noSQL databases make use of less constrained consistency models to gain simplicity of design, horizontal scalability and finer control over availability. NoSQL databases are schema free and are capable of distributing data among different computers. Insert and search throughput is related to the number of computers in which the data is stored.
This gives them the ability to horizontally scale up, while relying on relatively simple APIs. Therefore scalability is achieved by adding computers to the cluster rather than improving the existing hardware. Crash recovery and high availability are obtained by data replication, a configuration similar to the well-known master-slave SQL configuration. Moreover, queries can be distributed among the different computers that hold the data in order to improve the performance. All these make noSQL database management systems quite useful when working with large datasets or when the nature of the data does not require a relational model.

However, ACID which is guaranteed in SQL database transactions, is typically not directly provided by noSQL databases. In particular, consistency is guaranteed only after a period of time sufficient to propagate the changes through the system. Thus, the management of noSQL databases is usually quite more cumbersome than that of SQL ones.

Finally we would like to note than in order to improve the search performance on both relational and non relational databases, it is important to index the data fields which are used more frequently for classification.

### 2.2 Documents format and storage

Typically we download more than 15 million statuses (tweets) per day, and this number grows over the time. However, the volume of tweets is not constant in time. Political or social singular events can cause traffic spikes, thus the database must have the ability to handle large and steadily increasing volume of data while providing enough flexibility to deal with unexpected traffic peaks. In addition, the format of the information contained in tweets can, and does, change over the time.

The data we retrieve from Twitter is either encoded as JavaScript Object Notation (JSON), [JSON] or it can be easily converted to JSON format by using jsonpickle package [jsonp]. JSON format is used to transmit human readable data through a network connection as an alternative to XML. The attributes of JSON encoded objects are unsorted and the format of the attributes is not fixed. JSON flexibility allows for new fields to be added or old fields to be removed, and also to change the format of the fields (integer, string, datet ime, ... ).

Scalability and read/write performance drive us to consider noSQL databases to store documents. CouchDB [CouchDB], and MongoDB [MongoDB], have been considered in the study. Both databases are quite similar. On both, replication and failover security is achieved by replicating data on different servers. The advantages of CouchDB include that it accepts JSON data, ACID performance and allowing the use of map/reduce operations for query parallelization. However, queries have to be predefined in advance and users can only perform predefined queries or combinations of them. This is an inconvenient when the users of the database have different needs and objectives. Besides the language for the queries is quite specific and different from standard SQL commands.

On the other hand, MongoDB also accepts JSON data which is internally stored as a BSON [BSON] object, which is a JSON-like document in a binary format. MongoDB does not require the queries to be predefined and furthermore it supports SQL-like commands including aggregation of the results. Besides it also supports map/reduce queries. Furthermore it provides a large variety of indexes including geo indices, which is particular relevant for the kind of data queries we are interested in since it allows queries to be executed in real time. Even that MongoDB lacks real ACID transactions, it is more suitable when using large amounts of data. Horizontal scalability is much clear in MongoDB and the possibility to allow users to run their own queries without requiring predefinitions made MongoDB more suitable to our needs. In what follows the only noSQL database that is considered is MongoDB.

### 2.3 MongoDB configuration

MongoDB minimal configuration involves two computers, one server with all the data and one client to which the user application connects to. This minimal configuration does not ensure failover recovery. To ensure this, one needs additional computers forming a cluster. This cluster is called Replica Set and these groups consist of a minimum of three computers one of them designated as the primary and the others as secondaries. To ensure automatic failover recovery, the members of the replica set run a daemon that replicates the data. The primary member receives all the write/insert connections while secondaries replicate from the primary asynchronously with a delay of milliseconds and can receive read orders. Even that data replication uses much more space that the one really needed, it ensures high availability and increases read capacity. Apart from that, a good practice is to configure one of the secondary computers of each replica set with a predefined replication delay time and use it as backup. The standard MongoDB configuration hides the backup computer from clients so that it can not be used for searches to prevent searching in a non up to date data set.

The configuration with a single Replica Set is suitable when one single computer can store all the data and the read/write performance using a single computer is enough. In MongoDB the way to scale up the database is sharding: the collection of data is partitioned by using a key defined by the database administrator and the different chunks or portions are stored in different replica sets or shards. Sharding automatically balances data and load across the shards and increases write and read capacity. In addition to that, it provides a clear pathway to grow. When a database collection becomes too large for the existing configuration, a new shard (horizontal scalability) can be added and MongoDB automatically distributes collection data to the new group of servers.

In addition to shards or replica sets, in a sharded cluster there are configuration servers (CS) that store metadata relating replica sets with data portions and that route reads and writes from mongo clients (CL) to the appropriate replica set. Notice that client applications connect to mongo client (CL) which returns the answer to the queries. The structure behind is hidden to the client.

In our case (Fig. 1), we configured a sharded cluster with six replica sets formed by three members each. As recommended
in production environments, we are currently using three configuration servers. Each of the replica sets has two eligible primary members and the third one is a delayed copy by 72 hours. This gives us failover security because if primary server daemon crashes or stops, the secondary one becomes primary. The third member helps us to recover from human errors such as inadvertently deleted databases or botched application upgrades. Finally, the shard key used is the tweet identifier and we added indices by user identifier and latitude/longitude to speed up usual queries.

To improve writing performance we took into account several MongoDB features when customizing the operating system in the servers that form the replica sets.

3 DATA ACQUISITION

Even that Twitter provides mechanisms to retrieve only a small fraction of total amount of tweets (about 1% randomly distributed), this constitutes a large amount of data distributed all over the world. About 12% of the retrieved tweets have geolocated data. And only a small part of these are located in the cities we are focusing in, such as London or Barcelona. As a consequence, the number of tweets that can be used to study the human mobility in these cities is limited. To solve this issue, we select a set of users from the random sample which have tweets geolocated in the metropolitan areas and we download their timeline.

3.1 Twitter APIs

Twitter data access can be achieved through two ad hoc APIs that represent different Twitter features: Stream and Representational State Transfer (REST). The ‘Stream API’ is focused in data mining providing the real time sample of the tweets. The ‘REST API’ enables developers to access some of the core primitives of Twitter including timelines, status updates, and user information.

Although possible, directly access the Twitter APIs is not trivial. Therefore it is recommended to use a library [Twilib]. There are libraries for many computer languages although here we focus on Python. The code readability, the smooth learning curve, the quick development or the dynamic typing makes Python a suitable language to be used by software engineers and scientists. Among the libraries for Python we use the tweepy [Tweepy], for its simplicity and flexibility. Besides with a package we can access both Stream and REST APIs. Furthermore, it is open source (MIT License).

The data we receive from streaming is JSON encoded while the data we gather from other APIs is converted to JSON format by usingjsonpickle package [jsonp].

3.2 Random sample

Connecting to the streaming API requires having a Twitter account and keeping open a persistent HTTP connection to one of the public endpoints. Streaming API do not support requests. Randomly sampled tweets are provided automatically (subject to the limitation of about 1% of the total tweets). This API limits each account to just one standing connection. In fact, connecting to a public stream more than once with the same credentials causes the oldest connection to be disconnected. Besides, IPs of clients that make excessive connection attempts run the risk of being automatically banned.

As the process that opens the connection receives raw tweets, it has to perform all parsing, filtering, and aggregation needed before storing the result.

A particularity of the Streaming API is that messages are not delivered in the same precise order as they were generated. In particular, messages can be slightly shifted in time and it is also possible that deleted messages are received before the original tweet. This is not critical for the case considered here because we are interested in slower time scales (from minutes to hours) and therefore we do not need to have an exact timing and order of the messages.

In our case, connections to Twitter API are achieved by using tweepy. It allows the implementation of a listener that activates when a tweet arrives and so that it can be processed. Prior to the connection to the API it is necessary to provide the user authentication and to instantiate the listener.

A example of the code to simply print the tweets to the standard output is:

```python
from tweepy import Stream, OAuthHandler
from tweepy.streaming import StreamListener

class BasicListener(StreamListener):
    """
    A listener handles tweets are the received from the stream.
    """
    def on_data(self, data):
        # print received tweet to stdout
        print data
        return True

    def on_error(self, status):
        # print error when data is not correctly received
        print "Error: " + status
```

We identify the users which have tweets geolocated in the
3.3 Users selection
We identify the users which have tweets geolocated in the
metropolitan areas under study. Since we are interested in
people that moves, we first disregard all the users whose tweets
come always from the same location. This also filters out most
of advertising tweets send by companies, since they have a
fixed location. Then we sort users to be checked by number
of geolocated tweets already collected in order to prioritize
the most active ones.
Identification of geotweets located in the areas of interest is
achieved by using geoNear MongoDB command, [geoNear]
which returns the documents with a location not exceeding
a given distance (radius) from a given place. An example of
how to use geoNear command with MongoDB Python driver is
db.command(SON([('geoNear', collection),
                   ('near', [lon, lat]),
                   ('maxDistance', max_dist),
                   ('num', max_num_results)]))

MongoDB limits the size of the results document returned
by the geoNear query to 16MB. To avoid exceeding this
limitation we use a value for the radius of exploration of one
mile. To cover the metropolitan area we make use of a fine
grained mesh in which the points are separated by one mile
and perform geoNear query at each grid point.

3.4 Users wall
Retrieving the tweets posted by a specific user is done using
user_timeline method of the REST API to which we connect
via tweepy. In order to connect to this API we use an access
token generated by Twitter. In current version of the API, 1.1,
there is a limit in the number of queries per access token
and per method on a time window [limit]. For the queries
regarding user_timeline the limit is set to 180 requests every
fifteen minutes, [timeline]

Some users have their tweets protected. This implies that
while these tweets are freely distributed via streaming, it is not
possible to retrieve them via the REST API. Therefore when
we detect that a user protects its tweets, we remove him/her
from the list of selected users.
The method user_timeline returns a collection of the most
recent tweets posted by the user indicated by the user_id
parameter. These tweets are stored in a separate collection
from the one used for the stream API on the same MongoDB
database. In order to retrieve the maximum possible tweets
and to avoid having duplicated data, we request tweets with
an identifier higher than the highest tweet id we have for that
user. The user_timeline method can return a maximum of 200
historical tweets per query and in the case of very active users
some tweets can be lost.

An example of use on how to connect to the API and getting
the timeline:
from tweepy import OAuthHandler, API
...
OAuth = OAuthHandler(CONSUMER_KEY, CONSUMER_SECRET)
OAuth.set_access_token(ACCESS_KEY, ACCESS_SECRET)
tAPI = API(OAuth)
timeline = tAPI.user_timeline(count=200, user_id=uid,
                                      since_id=last_id)

3.5 Users network
Retrieving the user network can be also done through the REST
API. To do so we query for the list of user identifiers the
specified user is following, or [friends], and for the list of users
the user follows (reads the wall, [follow]) at the moment we
do the query.
Queries to each method are limited to 15 requests every
fifteen minutes. In order to study the network evolution, we
perform periodic queries for the different users within the
limitations the API imposes.
The code to get the followers and friends is:
tAPI.friends_ids(uid)
tAPI.followers_ids(uid)

4 Data insertion
We discuss here the procedure to insert the JSON documents
retrieved from Twitter into a relational database, such as
MySQL, and in MongoDB.

4.1 MySQL
When using MySQL, JSON data cannot be directly inserted
into the database. Therefore it is necessary to parse JSON to
a relational model. In particular we have to map the fields
in the JSON document to variables in classes. To do that,
we take advantage of Django Object Relational Model, ORM,
[Django]. First, one creates an empty Django project and then,
one sets the database connection information in the project
configuration file, settings.py. The database information to be
included in settings.py is the following:
Databases = {
    'default': {
        'ENGINE': 'django.db.backends.mysql',
        'NAME': 'twitterdb',
        'USER': 'theuser',
        'PASSWORD': 'thepassword',
        'HOST': 'mysqlHost',
        'PORT': '3360',
    }
}

In the project’s application, one creates a relational model with some classes (Tweet, User, HashTag, URL, ...). Primary keys and relations between registers are used to avoid data duplication. An example of the Tweet model class, which is the main one, is:

class Tweet(Model):
    twid = BigIntegerField(primary_key=True, db_index=True)
    place = ForeignKey(Place, null=True)
    text = CharField(max_length=2048, blank=True)
    retweet_count = IntegerField(null=True)
    parent_id = BigIntegerField(null=True)
    source = CharField(max_length=2048)
    coordinates = ForeignKey(BoundingBox, null=True)
    contributors = CharField(max_length=2048, null=True)
    retweeted = BooleanField()
    truncated = BooleanField()
    created_at = DateTimeField(null=True)
    user = ForeignKey(User)
    entities = ForeignKey(Entities, null=True)
    in_reply_to_status_id = BigIntegerField(null=True)
    in_reply_to_user_id = BigIntegerField(null=True)
    in_reply_to_screen_id = BigIntegerField(null=True)
    deleted = BooleanField()

class Meta:
    app_label = 'twitter'

Similarly for the class User, HashTag, URL, ...

Note that when generating the user key the Tweet class we make use of the ForeignKey class, so that if the user has already given a key, no new key is generated, instead a link to the existing register is performed. While this reduces the volume of data to be stored, it implies a search for each new tweet on the user index of the database to find out if the user is already there. Similarly we also use ForeignKey for place, coordinates and entities keys and therefore it is necessary to do a search on the corresponding index of the database for each new tweet.

Finally, for every JSON document, a parsing function is needed to store the data into the database. A sample of the parsing function is:

def fillTweet(jsondata):
    t = Tweet()
    if propertyExists(jsondata, "delete"):
        logger.info("Deleted tweet")
        # do some magic
    else:
        logger.info("New tweet")
        twlist = Tweet.objects.filter(twid=jsondata["id"])
        if len(twlist) == 1:
            logger.info("already added")
        t.twid = jsondata["id"]
        t.user = fillUser(jsondata)
        t.coordinates = fillPointBBox(jsondata)
        t.created_at = fillCreatedAt(jsondata)
        t.entities = fillEntities(jsondata)
        t.in_reply_to_screen_id = fillReplyScreen(jsondata)
        t.in_reply_to_status_id = fillReplyStatus(jsondata)
        t.in_reply_to_user_id = fillReplyUser(jsondata)
        t.place = fillPlace(jsondata)
        t.retweeted = fillRT(jsondata)
        t.source = fillSource(jsondata)
        t.text = fillText(jsondata)
        t.truncated = fillTruncated(jsondata)
        t.twid = jsondata["id"]
    return twlist[0].twid

collection = db[collectionname]

Where collectionname designs the collection to which the documents are to be inserted.

Since MongoDB accepts JSON documents no preprocessing is needed for the tweets downloaded from the Streaming API. So, one connects to the stream collection and inserts directly the document:

collection.insert(json_tweet)

The user_timeline method of the REST API returns a Python object which can be easily converted to a JSON document and then inserted in the timeline collection.

pickled = jsonpickle.encode(python_tweet)
json_tweet = json.loads(pickled)
collection.insert(json_tweet)

5. DATABASE INSERTION PERFORMANCE

We first analyse the insertion rate performance for MySQL and MongoDB. The physical computers we used had two Xeon L5520 at 2.27GHz processors with a total of 8 cores, 16GB of DDR3 RAM and a 2TB hard disk (7200rpm).

5.1 MySQL

In Figure 2 the green line shows the time to insert 100000 tweets in a completely empty MySQL database running on a...
single physical computer. As explained above, when inserting tweets in MySQL, as it is a relational database, we first perform several searches to find if the Twitter low level entities such as user, hashtag, URL, ... exist, which results in a larger storage time. As shown in 2, as the database grows the searches take longer and the insertion rate decreases. It takes 1000 s when it is empty, above 1500 s when there are four million tweets and almost 4000 s when the database has twelve million tweets.

To avoid this search issue, we tested the same insertion procedure without using ForeignKey, so that no searches are performed. For instance the corresponding lines of the Tweet class would read:

```python
coordinates = BoundingBox()
...
user = User()
entities = Entities()
```

As a consequence, in this case one does not takes advantage of the relational properties of the database and duplicates data. The results are shown as a red line in Fig. 2. The insertion rate is almost constant while inserting 4 million tweets. The insertion rate, in fact, slightly reduces when the database is over 15 million tweets.

5.2 MongoDB

Figure 3 shows the time needed to insert 100000 tweets in a MongoDB database with three shards (replica sets) using a single client. Here, instead of starting with an empty database, we tested the performance with a database that had already 850 million documents stored. As can be seen, storage time is much smaller that in MySQL, around 500 s for the 100000 tweets, which is a speed up factor of two with respect to the MySQL when no search is performed. Although the speed up is smaller than the factor three expected from the fact of having three replica sets, it is still substantial. What is more important, since we do not need to perform searches, this performance is maintained as the database size grows.

6 MongoDB query performance

Here we analyse the response time of MongoDB when queries are performed. MongoDB allows to configure the queries to be performed on the primary nodes or on the secondary ones. This flexibility is particularly convenient in situations where data is continuously inserted, as the case considered here, since one can configure the system so that queries are performed on the secondary nodes leaving the insertion data rate unaffected.

Since our goal is to analyse the geolocated tweets stored in the database we focus on MongoDB spatial indexing and querying. MongoDB offers a specific geospatial index 2d for data stored as points on a two-dimensional plane. The 2d index supports distance calculations on a sphere but not more complex calculations. As of version 2.4 MongoDB also includes the index 2dsphere which conveniently supports queries that calculate geometries on a sphere. This index supports data stored as GeoJSON objects which is the way geospatial data is stored in the tweets. Even that 2dsphere
As discussed above we consider a mesh of points separated by one mile to cover the metropolitan area under study and perform a `geoNear` query at each grid point. Fig. 5 shows the histogram of the response time to `geoNear` queries in a database with 850 million documents stored. Although the response time to a small group queries was slow, more than thirty seconds, the average (red blue line) is just of three seconds, and in 70% of the queries to get the tweets localized in a radius of one mile of a given point lasted less than nine seconds (red vertical line).

### 7 Preliminary Results for Mobility Patterns

Preliminary results after retrieving data for ten months show a good agreement with population in London and Barcelona metropolitan areas and the transportation network of these cities (see Fig. 6 and 7). This means that ten months sampling is representative of the mobility in these areas.

In order to further assess that the data is statistically correct we plan to compare the statistics obtained from the first ten months with the ones obtained after two years.

Finally, in the framework of the European project EUNOIA [Eunoia], Twitter data amongst other data will be used to characterise and compare mobility and location patterns in different European cities. Besides, urban land use and transportation models will be studied by integrating the role of the social network and new models of joint trips and joint resource use.

### 8 Concluding Remarks

In summary, we have presented an example of efficient social networks data acquisition and storage by using Python programming language and specific packages to connect user's applications to Twitter APIs and to MongoDB distributed non relational database.
