(Dated: February 20, 2018)

We present a spin-rotation-invariant Green-function theory for the dynamic spin susceptibility in the spin-1/2 antiferromagnetic Heisenberg model on a stacked honeycomb lattice. Employing a generalized mean-field approximation for arbitrary temperatures, the thermodynamic quantities (two-spin correlation functions, internal energy, magnetic susceptibility, staggered magnetization, Néel temperature, correlation length) and the spin-excitation spectrum are calculated by solving a coupled system of self-consistency equations for the correlation functions. The temperature dependence of the magnetic (uniform static) susceptibility is ascribed to antiferromagnetic short-range order. The Néel temperature is calculated for arbitrary interlayer couplings. Our results are in a good agreement with numerical computations for finite clusters and with available experimental data on the \(\beta\)-Cu\(_2\)V\(_2\)O\(_5\) compound.

I. INTRODUCTION

In recent years the low-dimensional quantum Heisenberg antiferromagnets have been extensively studied motivated by experimental research of such systems. In particular, there is a vast literature devoted to the study of the two-dimensional (2D) antiferromagnetic Heisenberg model (AFHM) on the square lattice initiated by the discovery of AF long-range order (LRO) in high-temperature superconductors (for a review see [1]). According to the Mermin-Wagner theorem [2], in 2D isotropic Heisenberg magnets quantum spin fluctuations destroy the magnetic LRO at finite temperature. However, it has been shown that for the spin-1/2 2D AFHM with nearest-neighbor (nn) interaction on the square lattice, LRO can occur at zero temperature, while at finite temperature only the exponential increase of the AF correlation length with decreasing temperature is observed [3]. For the 2D honeycomb lattice with the lower coordination number \(z = 3\), quantum spin fluctuations are more intensive and detrimental for the occurrence of LRO. Studies of the frustrated Heisenberg model with the AF interaction between the second-nearest \((J_2)\) and the third-nearest \((J_3)\) neighbors on the honeycomb lattice have revealed several phases with LRO, and a more complicated phase diagram occurs. For instance, using the coupled cluster method [4, 5], in the \(J_1 – J_2 – J_3\) Heisenberg model on the 2D honeycomb lattice four competing magnetic phases (Néel, stripe, Néel-II collinear AF, and spiral phases) were found depending on the model parameters. Much attention has been paid to studies of the 2D Kitaev-Heisenberg model with the isotropic nn interaction \(J\) and the bond-depending Kitaev interaction \(K_\alpha\) [6]. Besides the spin-liquid Kitaev phase at \(J = 0\), a rich phase diagram at zero temperature with competing LRO (ferromagnetic, AF, stripe and zigzag phases) emerges (see, e.g., [4, 5]). In a model with anisotropic \(K_\alpha\) interactions, e.g., \(K_\alpha > K_\beta = K_\gamma\), the LRO survives at finite temperature as shown in Ref. [6].

For the isotropic 2D honeycomb Heisenberg model with nn AF interaction, the LRO at zero temperature, similar to the square lattice, was confirmed in a number of studies mostly performed for finite-lattice systems. The ground-state energy \(E_0\), staggered magnetization \(m_{st}\), uniform static susceptibility \(\chi(0)\) at \(T = 0\), and other properties of the 2D honeycomb AFHM were calculated using various methods, such as extrapolations of finite-lattice diagonalizations and quantum Monte Carlo (QMC) simulations [10–13], spin-wave theory [13, 14], series expansions around the Ising limit [15, 16], Schwinger boson method [17], and variational RVB wave function approach [18]. In Ref. [19] it was suggested to consider the \(\beta\)-Cu\(_2\)V\(_2\)O\(_5\) compound as the best available experimental realization of the spin-1/2 AFHM on the honeycomb-like lattice. The system can be characterized by the nearly isotropic nn exchange interaction \(J = (60–66) K\) and the interlayer coupling \(J_z = 0.2J\) which results in the Néel temperature \(T_N \approx 26\) K.

Besides the honeycomb AFHM, the honeycomb Hubbard model has been studied too. In Ref. [20] the AF LRO was found for a single layer close to half-filling at large Coulomb repulsion \(U\), where the staggered magnetization \(m_{st} = 0.335\) was obtained. In Ref. [21], using the two-particle self-consistent approach for the Hubbard model on the honeycomb lattice, the semimetal to spin-liquid transition was found before the transition to the AF state.

The AFHM on the honeycomb lattice has been less well studied as compared with the same model on the square lattice. Most of numerical computations have been performed for 2D finite-lattice systems at zero temperature, where such computations for 3D systems are difficult to realize. Moreover, the thermodynamics at arbitrary interlayer coupling, e.g., the dependence of \(T_N\) on \(J_z\), is not yet developed. Therefore, analytical approaches which are capable to evaluate the thermodynamics of the
AFHM on the layered honeycomb lattice both in the AF phase and in the paramagnetic phase with a temperature-dependent AF short-range order (SRO) are desirable.

To this end, in this paper we present a theory of magnetic order in the honeycomb AFHM over the whole temperature region that is based on the calculation of the dynamic spin susceptibility (DSS) within the spin-rotation-invariant (SRI) relaxation-function theory \[22, 23\] using the generalized mean-field approximation (GMFA), as has been done in our study of the compass-Heisenberg model on the square lattice \[24\]. Using the result for the DSS, the staggered magnetization, the static spin susceptibility, the Néel temperature as a function of the interaction, and the spin-excitation dispersion both in the AF phase and in the paramagnetic phase are calculated self-consistently, where we pay particular attention to a proper description of AF SRO. It should be pointed out that the GMFA has been successfully applied to several quantum spin systems (see, e.g., Refs. \[25–43\]). In particular, let us mention an application of the GMFA to study the spin-1/2 AFHM on the stacked kagomé lattice \[42\], where no LRO was found even for a strong interlayer coupling due to the frustration character of the AF interaction on this lattice.

In Sect. II we formulate the model and give equations for the spin correlation functions and the spin-rotation-invariant (SRI) relaxation-function theory \[22, 23\] using the equation of motion method in Refs. \[22, 23\] we consider the retarded two-time commutator Green function (GF) \[44\]:

$$G_{ij,\alpha\beta}^{\nu}(t - t') = -i\theta(t - t')\langle [S_{i\alpha}^{\nu}(t), S_{j\beta}^{\nu}(t')]\rangle$$

$$= \langle S_{i\alpha}^{\nu}(t) | S_{j\beta}^{\nu}(t') \rangle,$$

(3)

where $[A, B] = AB - BA$, $A(t) = \exp(iHt)A\exp(-iHt)$, and $\theta(x)$ is the Heaviside function. In the SRI theory all GF components $\nu = x, y, z$ are equivalent; therefore, we consider only one of them, e.g., $\nu = x$. The Fourier representation in $(\mathbf{q},\omega)$-space is defined by the relation:

$$G_{ij,\alpha\beta}^{\nu}(t - t') = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} e^{-i\omega(t - t')}$$

$$\times \frac{1}{N} \sum_{\mathbf{q}} e^{i\mathbf{q}(\mathbf{R}_{i} - \mathbf{R}_{j})} G_{ij,\alpha\beta}^{\nu}(\mathbf{q},\omega),$$

(4)

where $N$ and $\mathbf{R}_{i}$ is the number and position of unit cells, respectively, and the GF matrix reads

$$G^{\nu}(\mathbf{q},\omega) = \left(\langle S_{qA}^{\nu}|S_{qA}^{\nu}\rangle_\omega \langle S_{qA}^{\nu}|S_{qB}^{\nu}\rangle_\omega \langle S_{qB}^{\nu}|S_{qB}^{\nu}\rangle_\omega \langle S_{qB}^{\nu}|S_{qA}^{\nu}\rangle_\omega \right).$$

(5)

In the relaxation-function theory developed on the basis of the equation of motion method in Refs. \[22, 23\] we obtain the following representation of the DSS $\chi(\mathbf{q},\omega) = -G^{\nu}(\mathbf{q},\omega)$:

$$\chi(\mathbf{q},\omega) = \left[F(\mathbf{q}) + \Sigma(\mathbf{q},\omega) - \omega^2 \tau_{0}\right]^{-1} \times m(\mathbf{q}).$$

(6)
Here, $F(q)$ is the frequency matrix of spin excitations in the GMFA, where the approximation $-\hat{S}^r = [[S^r_{\alpha\beta}, H], H] = \Sigma_\beta F_{\alpha\beta}(q) S^r_{\alpha\beta}$ is made, $\tau_0$ is the unity matrix, and $m(q)$ is the moment matrix with components $m_{\alpha\beta}(q) = \langle [i\hat{S}^r_{\alpha\beta}, S^r_{\alpha\beta}] \rangle = \langle [[[S^r_{\alpha\beta}, H], H], S^r_{\alpha\beta}] \rangle$. The self-energy $\Sigma(q, \omega)$ can be expressed exactly by a multi-spin GF (see Refs. 22, 23).

III. GENERALIZED MEAN-FIELD APPROXIMATION

We consider the GMFA for the DSS neglecting the self-energy $\Sigma(q, \omega)$ in Eq. (3). Then, for a lattice with basis the zero-order DSS is given by [42]:

$$[F(q) - \omega^2 \tau_0] \times \chi(q, \omega) = m(q).$$

For the static spin susceptibility we obtain

$$\chi(q, 0) = \chi(q) = F^{-1}(q) \times m(q).$$

The direct calculation of the matrix elements $m_{\alpha\beta}(q)$ yields

$$m(q) = \begin{pmatrix} m_{AA}(q) & m_{AB}(q) \\ m_{BA}(q) & m_{AA}(q) \end{pmatrix},$$

where

$$m_{AA}(q) = -6 JC_1 - 4 J_z C_z (1 - \cos q_z),$$

$$m_{AB}(q) = 2 J C_1 \gamma_1(q),$$

$$\gamma_1(q) = \sum_i \exp(iq \delta_i),$$

$$|\gamma_1(q)|^2 = 1 + 4 \cos(q_z) \cos(q_y).$$

From the symmetry of our model it is obvious that we have only two different nn correlation functions: $C_1$ within the plane and $C_z$ between neighboring planes.

To calculate the frequency matrix $F(q)$ in Eq. (7), we start from the second derivative $-\hat{S}^r$ that is proportional to products of three spin operators on different lattice sites along nn sequences, e.g., $(iA, jB, kA)$. We perform the decoupling of them as follows

$$S^{r}_{A}\ S^{y}_{B}\ S^{y}_{A} = \alpha_1 (S^{y}_{B}\ S^{y}_{A})_A S^{r}_{A} = \alpha_1 C_1 S^{r}_{A},$$

$$S^{r}_{B}\ S^{y}_{A}\ S^{y}_{A} = \alpha_2 (S^{y}_{B}\ S^{y}_{A})_A S^{r}_{B} = \alpha_2 C_2 S^{r}_{B},$$

$$S^{r}_{B}\ S^{y}_{A}\ S^{y}_{A} = \alpha_3 (S^{y}_{B}\ S^{y}_{A})_A S^{r}_{B} = \alpha_3 C_z S^{r}_{B},$$

where the index $i + i_z$ denotes the unit cell with position $R_{i+i_z} = R_i + a_z$. Here the vertex renormalization parameters $\alpha_1$ and $\alpha_2$ are attached to the nn and the next-nn correlation functions $C_1$ and $C_2$ respectively. In the 3D case we introduce $\alpha_3$, associated with the nn interlayer correlation function $C_z$. For the next-nn correlation functions between the layers $C_z = \langle S^{r}_{A}\ S^{y}_{B}\ S^{y}_{A} \rangle$ and $C_{1z} = \langle S^{y}_{A}\ S^{y}_{B} \rangle$ we attach the same vertex parameter $\alpha_2$ as for the next-nn within the layer. Using these decouplings we obtain the frequency matrix $F(q)$:

$$F(q) = \frac{1}{2} \begin{pmatrix} F_{AA}(q) & F_{AB}(q) \\ F_{BA}(q) & F_{AA}(q) \end{pmatrix},$$

where

$$F_{AA}(q) = J^2 (3 + 24 \alpha_2 C_2 + 4 \gamma_2(q) \alpha_1 C_1) + 24 J_2 \alpha_2 C_1 (2 - \cos q_z) - \cos q_z \alpha_1 C_1,$$

$$F_{AB}(q) = -\gamma_1(q) f_{AB}(q), f_{AB}(q) = 2 J_2 \alpha_2 C_1 (2 - \cos q_z) + \alpha_2 C_1 \cos q_z \alpha_1 C_1,$$

$$F_{BA}(q) = \gamma_1(q) f_{AB}(q), f_{AB}(q) = 2 J_2 \alpha_2 C_1 (2 - \cos q_z) + \alpha_2 C_1 \cos q_z \alpha_1 C_1,$$

with

$$\gamma_1(q) = \sum \exp(iq \delta_i - \delta_j),$$

$$= 4 \cos(q_x) \cos(q_y) + 2 \cos(q_z).$$

Since the matrices $m(q)$ and $F(q)$ commute, it is convenient to solve Eq. (7) by introducing the eigenvalues $m_{\pm}(q)$ and the normalized eigenvectors $|E_\pm(q)|$ of the matrix $m(q)$:

$$[m(q) - \tau_0 m_{\pm}(q)] |E_\pm(q)| = 0,$$

which are given by

$$m_{\pm}(q) = -2 J C_1 (3 \pm |\gamma_1(q)|) - 4 J_z C_z (1 - \cos q_z),$$

$$|E_\pm(q)| = \frac{1}{\sqrt{2}} \left( \mp \gamma_1(q) \sqrt{|\gamma_1(q)|} \right).$$

For the same eigenvectors $|E_\pm(q)|$ the spin-excitation frequencies are obtained as

$$\omega^2_{\pm}(q) = \frac{1}{2} (F_{AA}(q) \pm |\gamma_1(q)| f_{AB}(q)).$$

In this notation the DSS reads:

$$\chi_\alpha(q, \omega) = \sum_{j=\pm} \chi_j(q, \omega) \langle \alpha | E_j(q) \rangle \langle E_j(q) | \beta \rangle,$$

where

$$\chi_\pm(q, \omega) = \frac{m_{\pm}(q)}{\omega^2_{\pm}(q) - \omega^2},$$

and $\langle \alpha | E_\pm(q) \rangle \langle E_\pm | \beta \rangle = 1/2$ for $\alpha = \beta$, otherwise

$$\langle \alpha | E_\pm(q) \rangle \langle E_\pm | \beta \rangle = \mp |\gamma_1(q)| / |\gamma_1(q)|).$$

Introducing the Fourier representation for the correlation function as in Eq. (4),

$$C_{ij,\alpha\beta} = \langle S^{r}_{i\alpha} S^{y}_{j\beta} \rangle = \frac{1}{N} \sum_{q} e^{iq (R_i - R_j)} C_{\alpha\beta}(q),$$

(21)
and using the spectral representation for the GF, we calculate the spin correlation function:

\[
C_{\alpha\beta}(q) = \langle S^\nu_{q\alpha} S^\nu_{q\beta} \rangle
= \sum_{j=\pm} \frac{m_j(q)}{2\omega_j(q)} \frac{1}{\cosh \left( \frac{\omega_j(q)}{2T} \right)} \langle \sigma_j(q) \rangle \langle E_j(q) | E_j(q) \rangle \beta. \quad (22)
\]

The correlation functions \(C_R\) are written as:

\[
C_{R,\alpha\beta} = \langle S^\nu_{q\alpha} S^\nu_{q\beta} \rangle
= \frac{1}{N} \sum_{q \neq Q} C_{\alpha\beta}(q) e^{i\mathbf{q}\cdot\mathbf{R}} + C_{\alpha\beta} e^{iQ\mathbf{R}},
\]

where \(C_{\alpha\alpha} = -C_{\alpha\beta} = C\), and the wave-vector \(Q\) characterizes the LRO. The condensation part \(C\) appears in the ordered phase when \(\omega_+(q)\) condensates at \(Q\) which determines the LRO, \(\omega_+(Q) = 0\). In the case of AF order in the two-sublattice model we have \(Q = (0,0,\pi)\), and the staggered magnetization \(m_{st}\) is determined by

\[
(m_{st})^2 = 3C.
\]

Let us consider the uniform static susceptibility \(\chi = \chi_{AA}(0) + \chi_{AB}(0) = \chi_{-}(0)\) and the staggered susceptibility \(\chi_{st} = \chi_{AA}(Q) - \chi_{AB}(Q) = \chi_{+}(Q)\). Expanding \(\chi_-(q)\) around \(q = 0\) we get

\[
\chi = \frac{-4C_1}{J + 2J\alpha_1 C_1 + 8J\alpha_2 C_2 + 8Jz_2(\alpha_2 C_{1z} - \alpha_1 C_1)}. \quad (25)
\]

Considering \(q \rightarrow 0\) from different directions in momentum space we can write the isotropy condition for the uniform static susceptibility which should not depend on the direction of \(q \rightarrow 0\): \(\lim_{q \rightarrow 0} \chi_-(q)_{q_{x,y}=0} = \lim_{q_{x,y}=0} \chi_-(q)\) (see Refs. [29, 30, 35, 38, 42]). This condition gives us the relation between the intralayer and interlayer correlation functions:

\[
\frac{-4C_1}{1 + 2\alpha_1 C_1 + 8\alpha_2 C_2 + 8(Jz/J)(\alpha_2 C_{1z} - \alpha_1 C_1)} = \frac{-2C_z}{2\alpha_2 C_{1z} - \alpha_2 C_2} + (Jz/J)(1 + 4\alpha_2 C_{zz}). \quad (26)
\]

We expand \(\chi_+(q)\) in the neighborhood of the AF vector \(Q\) and obtain \(\chi_+(Q + k) = \chi_+(Q)[1 + \xi_{xy}^2(k_x^2 + k_y^2) + \xi_{zz}^2(k_z^2)]^{-1}\), where for the intralayer correlation length \(\xi_{xy}\) we get:

\[
\xi_{xy}^2 = \frac{1}{2\omega_{xy}(Q)} J^2(3 + 42\alpha_1 C_1 + 24\alpha_2 C_2)
+ 24(Jz/J)(2\alpha_2 C_{zz} + \alpha_2 C_{1z} + \alpha_1 C_1). \quad (27)
\]

At zero temperature in the 2D case or at \(T = T_N\) in the 3D case, the LRO occurs when both the correlation length (27) and \(\chi_+(Q)\) diverge.

### IV. RESULTS

To evaluate the spin-excitation spectrum and the thermodynamic properties, the correlation functions \(C_{R,\alpha\beta}\) and the vertex parameters \(\alpha_1\), \(\alpha_2\), and \(\alpha_z\) appearing in the spectrum \(\omega_+(q)\) as well as the condensation term \(C\) in the LRO phase have to be determined as solution of a coupled system of self-consistency equations. Besides Eq. (23) for calculating the correlation functions, we have the sum rule \(C_{R=0,\alpha\alpha} = \langle S^\nu_{q\alpha} S^\nu_{q\alpha} \rangle = 1/4\), the isotropy condition (25), and the LRO condition \(\omega_+(Q) = 0\). That is, we have more parameters than equations. To obtain a

FIG. 2: Correlation functions \(C_1\) (solid line) and \(C_2\) (dashed line) at \(J_z = 0\) versus temperature. The inset shows the vertex renormalization parameters \(\alpha_1\) (solid) and \(\alpha_2\) (dashed).
closed system of equations, we adjust the staggered magnetization at $T = 0$ to the QMC values $m_{st}(0) = 0.2681$ for $J_z = 0$ and $m_{st}(0) = 0.41$ for $J_z = J$ [11], where we take the latter value in the region $0 < J_z < 1$. For finite temperatures we follow Refs. [26, 28, 30, 31, 38] and use the ansatz $r_{\alpha}(T) \equiv \frac{\alpha_2(T) - 1}{\alpha_1(T) - 1} = r_{\alpha}(0)$.

The results of our self-consistent calculations are presented in Table I and in Figs. 2 - 8. As can be seen from Table I, our results for the ground-state energy $E_0/JN_s$ per site and for the zero-temperature uniform static susceptibility $\chi(0)$ rather well agree with the calculations by various methods. Note that the ground-state energy per site taken from Ref. [11], $E_0/JN_s = -0.5445$, is related to the ground-state energy $e_0/J$ per bond, $e_0/J = -0.36303$ obtained in Ref. [11], by $E_0/N_s = \frac{2}{3}e_0$. In Fig. 2 the nn and next-nn correlation functions in the 2D model are plotted. With increasing temperature the AF SRO, reflected in alternating signs of $C_1$ and $C_2$, is weakened which corresponds to a decrease of the correlation functions and vertex parameters (see inset of Fig. 2).
FIG. 7: Spin-excitation spectrum at $J_z = 0$: $\omega_-(q) \ (\text{solid})$ and $\omega_+(q) \ (\text{dashed})$ for (a) $T = 0$ and (b) $T = 0.6J$.

FIG. 8: Spin-excitation spectrum at $J_z = 0.2J$: $\omega_-(q = 0) \ (\text{solid})$ and $\omega_+(q = \pi) \ (\text{dashed})$ for (a) $T = 0$ and (b) $T = 0.6J$.

The uniform static spin susceptibility $\chi$ is shown in Fig. 3 for the 2D and 3D ($J_z = J$) cases. The increase of $\chi$ with temperature is due to the reduction of AF short-range correlations which is connected with a weakening of the spin stiffness against the orientation of spins along a homogeneous magnetic field. The further decrease of AF SRO results in a crossover to the high-temperature Curie-Weiss behavior, so that $\chi$ reveals a maximum at a temperature of the order of the exchange interaction $J$. For $J_z = 0$ we obtain the maximum value $\chi_{\text{max}} = 0.122/J$ at $T_{\text{max}} = 0.96J$. This is close to the QMC result of Ref. 11: $\chi_{\text{max}} = 0.117/J$ at $T_{\text{max}} = 0.72J$. In the 3D case with $J_z = J$ our results for the temperature dependence of $\chi$ in Fig. 3 are in a very good agreement with the QMC calculations in Ref. 11. The interlayer coupling $J_z > 0$ lowers the susceptibility and slightly shifts the maximum of $\chi$ to higher temperatures in comparison with the 2D case, which is due to the $J_z$-induced enhancement of AF SRO. Let us compare the maximum temperature $T_{\text{max}}$ with the value obtained by susceptibility experiments on the the $\beta$-Cu$_2$V$_2$O$_2$ compound, $T_{\text{exp}} = 50K$ [13]. Taking $J = 60K$ [19] we get $T_{\text{max}} = 58K$ which is near to the experimental value.

In Fig. 4 the staggered magnetization $m_{\text{st}}$ is depicted. It reveals a second-order transition to the AF phase below the Néel temperature $T_N$. For $J_z = 0.2J$ we obtain $T_N = 0.52J$, whereas the QMC simulations of Ref. 19 yield the lower value $T_{\text{QMC}} = 0.41J$. The inequality $T_{\text{QMC}} > T_{\text{exp}}$ was also found for the AFHM on the stacked square lattice [33]. Considering $\beta$-Cu$_2$V$_2$O$_2$ with $J_z = 0.2J$ and $J = (60–66)K$ [19] we have $T_N \approx (30–35)K$ that is close to the experimental value $T_{\text{exp}} = 26K$ [13]. For $J_z = J$ we find $T_N = 0.78J$ and a good agreement of the temperature dependence of $m_{\text{st}}$ with the QMC data for the largest system size obtained in Ref. 11.

The Néel temperature as a function of the interlayer coupling $J_z$ is shown in Fig. 5 where $T_N$ reveals the strongest decrease with decreasing $J_z$ for $J_z/J \ll 1$ and tends to zero logarithmically for $J_z \to 0$. The $J_z$ dependence of $T_N$ in the region $0 \leq J_z \leq 0.2J$ can be approximated with the accuracy of 1% by the formula

$$T_N \approx \left( \frac{T_{\text{exp}}}{J} \right) \left( 1 - \frac{J_z}{J} \right) \left( \frac{A}{B - \ln(J_z/J)} \right),$$

where $A = 1.48$, $B = 1.25$. This behavior resembles the empirical formula proposed in Ref. 40 and the result of Refs. 38, 43. Note that qualitatively the same law with $\lim_{J_z \to 0} OT_N/\partial J_z = \infty$ was also found in the random phase approximation (see Ref. 38).

In Fig. 6 the influence of the interlayer coupling on the temperature dependence of the intralayer correlation length $\xi_{xy}$ is illustrated. In the 2D case, $\xi_{xy}$ diverges exponentially at $T = 0$. For $J_z > 0$, $\xi_{xy}$ diverges at $T_N$, since the gap $\omega_+(Q)$ closes as $T$ approaches $T_N$ from above. In the vicinity of $T_N$, $\xi_{xy}^{-1}$ behaves as $T - T_N$ (corresponding to the critical index $\nu = 1$), as it was also found by previous mean-field approaches (see Refs. 30, 38).

The spectrum of spin excitations $\omega_\pm(q)$ is shown in Figs. 7 and 8 along the symmetry directions $X(-1, 0) \to \Gamma(0, 0) \to Y(0, 1) \to \Gamma'(1, 1) \to M(1/2, 1/2) \to \Gamma$ of the BZ using the same notation as in Ref. 3. In the LRO phase, i.e., for $T = 0$ at $J_z = 0$ and for $T < T_N = 0.52J$ at $J_z = 0.2J$, the spin excitations are spin waves with gapless branches depicted in Fig. 7(a) and 8(a). In the paramagnetic phase, spin waves propagating in AF SRO can exist, if their wavelength is smaller than the correlation length, i.e., if $q > q_c = 2\pi \xi^{-1}$. For temperatures slightly above the transition temperature, where
In the upper (optical) branch, at the Γ point, i.e., at the AF wave vector $Q$, one has to determine the self-energy, as has been done in Refs. [23]. As it turns out, in the square-planar complexes given in Ref. [47]. For example, by resonant inelastic x-ray scattering on high-$T_c$ superconductors [48, 49]. In Fig. 8(b), due to the lower value of $q_c$, we have $q > q_c$, where the spin excitations are high-energy magnons. Thus, our spin-excitation spectra reveal a smooth crossover from spin-wave to paramagnon behavior depending on the wave number and temperature. In the upper (optical) branch, at $T_N$ a gap is opening at the Γ point, i.e., at the AF wave vector $Q$ characterizing the LRO phase in the two-sublattice model ($Q = (0,0)$ at $J_z = 0$ and $Q = (0,0,\pi)$ at $J_z > 0$). As can be seen in Figs. 7 and 8, the spin-excitation energies are decreasing with increasing temperature. Let us point out that the spectrum of spin excitations is calculated in the GMFA which neglects finite-time effects. To take them into account, one has to determine the self-energy, as has been done in Refs. [23]. As it turns out, in the square-lattice Heisenberg model the damping of spin excitations is quite small. Therefore, we believe that in our model the inclusion of damping will not qualitatively change our results for the spin-excitation spectrum. Provided that a spin-1/2 antiferromagnet with a real honeycomb-lattice structure may be found, it is desirable to confirm our findings on the optical branch $\omega_+(q)$ by scattering experiments, where the intensity of the scattering is determined by the staggered susceptibility $\chi_+(Q)$ given by Eq. (20), so that the gap $\omega_+(Q)$ may be measured.

V. CONCLUSION

In this paper we have evaluated thermodynamic quantities and spin-excitation spectra of the AF Heisenberg model on the stacked honeycomb lattice by calculating the dynamic spin susceptibility within a spin-rotation-invariant generalized mean-field approach for arbitrary temperatures. Our main focus was the analysis of the temperature dependence of the uniform static susceptibility in the paramagnetic phase, which we have explained in terms of AF SRO, and the calculation of the Néel temperature in dependence on the interlayer coupling. Our results are in a good agreement with available QMC and experimental data. From this we conclude that our investigation forms a good basis for forthcoming studies of extended layered honeycomb Heisenberg models (e.g., hole hopping).

Acknowledgments

The authors would like to thank J. Richter for valuable discussions. The financial support by the Heisenberg-Landau program of JINR is acknowledged. One of the authors (N. P.) thanks the Directorate of the MPIKFS for the hospitality extended to him during his stay at the Institute.
