Abstract

We describe the implementation of a FrameNet-based semantic role labeling system for Swedish text. To train the system, we used a semantically annotated corpus that was produced by projection across parallel corpora. As part of the system, we developed two frame element bracketing algorithms that are suitable when no robust constituent parsers are available. Apart from being the first such system for Swedish, this is, as far as we are aware, the first semantic role labeling system for a language for which no role-semantic annotated corpora are available. The estimated accuracy of classification of pre-segmented frame elements is 0.75, and the precision and recall measures for the complete task are 0.67 and 0.47, respectively.

1. Introduction

Automatic extraction and labeling of semantic arguments of predicates, or semantic role labeling (SRL), has been an active research area during the last few years. SRL systems have proven useful in a number of NLP projects. The main reason for their popularity is that they produce a flat layer of semantic structure with a fair degree of robustness. Building SRL systems for English has been studied widely (Gildea and Jurafsky, 2002; Litkowski, 2004), inter alia. However, all these works rely on corpora that have been produced at the cost of a large effort by human annotators. The current FrameNet corpus, for instance, consists of 130,000 manually annotated sentences. For smaller languages such as Swedish, such corpora are not available.

In this work, we used an English-Swedish parallel corpus whose English part was annotated with semantic roles using the FrameNet annotation scheme (Baker et al., 1998). We then applied a cross-language transfer to derive an annotated Swedish part. This annotated corpus was used to train a complete semantic role labeler for Swedish. We evaluated the Swedish labeler by applying it to a small portion of the FrameNet example corpus that was translated manually.

1.1. Background to FrameNet

Frame semantics (Fillmore, 1976) is a framework that focuses on the relations between lexical meanings — lexical units — and larger conceptual structures — semantic frames, typically referring to situations, states, properties or objects. It comes as a development of Fillmore’s earlier theory of semantic cases.

FrameNet (Baker et al., 1998) is a comprehensive lexical database that lists frame-semantic descriptions of English words. It consists of a set of frames, which are arranged in an ontology using relations such as inheritance, part-of, and causative-of. Different senses of ambiguous words are represented by different frames. For each frame, FrameNet lists a set of lemmas (nouns, verbs, and adjectives). When a word occurs in a sentence, it is called a target word that evokes the frame.

Properties of and participants in a situation are described using frame elements (FEs), each of which has a semantic role from a small frame-specific set, which defines the relation of the FE to the target word.

In addition, FrameNet comes with a large set of manually annotated example sentences, which are typically used by statistical systems for training and testing. Figure 1 shows an example of such a sentence. In this example, the word statements has been annotated as a target word evoking the STATEMENT frame, as well as two FEs relating to the target word (SPEAKER and TOPIC).

As usual in these cases, [both parties] SPEAKER agreed to make no further statements [on the matter] TOPIC.

Figure 1: A sentence from the FrameNet example corpus.

1.2. Related Work

Cross-lingual induction of NLP tools by means of parallel corpora has been used in a number of projects. Hwa et al. (2002) applied a parser on the English part of a parallel corpus and projected the syntactic structures on texts in the second language. They reported results that rival commercial parsers. Yarowsky et al. (2001) describe a method for cross-language projection, using parallel corpora and a word aligner, that is applied to a range of NLP tasks, such as named entities and noun chunk bracketing.

Recently, these methods have been applied to FrameNet annotation. Padó and Lapata (2005), for instance, give a very careful and detailed study of methods of transferring semantic role information. However, they crucially rely on an existing FrameNet for the target language (in their case German) to select suitable sentence pairs, and the source-language annotation was produced by human annotators. Johansson and Nugues (2005) describe a similar experiment, but use an automatic method for annotating the English side.

A different method to construct bilingual semantic role annotation is the approach taken by BiFrameNet (Fung and Chen, 2004). In that work, annotated structures in a new language (in that case Chinese) are produced by mining for similar structures rather than using parallel sentences.
2. Automatic Annotation of a Swedish Training Corpus

2.1. Training an English Semantic Role Labeler
We selected the 150 most common frames in FrameNet and applied the Collins parser (Collins, 1999) to the example sentences for these frames. We built a conventional FrameNet parser for English using 100,000 of these sentences as a training set and 8,000 as a development set. The classifiers were based on Support Vector Machines that we trained using LIBSVM (Chang and Lin, 2001) with the Gaussian kernel. When testing the system, we did not assume that the frame was known a priori. We used the available semantic roles for all senses of the target word as features for the classifier.

On a test set from FrameNet, we estimated that the system had a precision of 0.71 and a recall of 0.65 using a strict scoring method. The result is slightly lower than the best systems at Senseval-3 (Litkowski, 2004), possibly because we used a larger set of frames, and we did not assume that the frame was known a priori.

2.2. Transferring the Annotation
We produced a Swedish-language corpus annotated with FrameNet information by applying the SRL system to the English side of Europarl (Koehn, 2005), which is a parallel corpus that is derived from the proceedings of the European Parliament. We projected the bracketing of the target words and the frame elements onto the Swedish side of the corpus by using the Giza++ word aligner (Och and Ney, 2003). Each word on the English side was mapped by the aligner onto a (possibly empty) set of words on the Swedish side. We used the maximal span method to infer the bracketing on the Swedish side, which means that the span of a projected entity was set to the range from the leftmost projected token to the rightmost. Figure 2 shows an example of this process.

To make the brackets conform to the FrameNet annotation practices, we applied a small set of heuristics. The FrameNet conventions specify that linking words such as prepositions and subordinating conjunctions should be included in the bracketing. However, since constructions are not isomorphic in the sentence pair, a linking word on the target side may be missed by the projection method since it is not present on the source side. For example, the sentence *the doctor was answering an emergency phone call* is translated into Swedish as *doktorn svarade på ett larmsamtal*, which uses a construction with a preposition *på* ‘to/at/on’ that has no counterpart in the English sentence. The heuristics that we used are specific for Swedish, although they would probably be very similar for any other language that uses a similar set of prepositions and connectives, i.e. most European languages.

We used the following heuristics:

- When there was only a linking word (preposition, subordinating conjunction, or infinitive marker) between the FE and the target word, it was merged with the FE.
- When a Swedish FE crossed the target word, we used only the part of the FE that was on the right side of the target.
- When a Swedish FE crossed the target word, we used only the part of the FE that was on the right side of the target.
- When a Swedish FE crossed the target word, we used only the part of the FE that was on the right side of the target.

In addition, some bad annotation was discarded because we obviously could not use sentences where no counterpart for the target word could be found. Additionally, we used only the sentences where the target word was mapped to a noun, verb, or an adjective on the Swedish side.

Because of homonymy and polysemy problems, applying a SRL system without knowing target words and frames a priori necessarily introduces noise into the automatically created training corpus. There are two kinds of word sense ambiguity that are problematic in this case: the “internal” ambiguity, or the fact that there may be more than one frame for a given target word; and the “external” ambiguity, where frequently occurring word senses are not listed in FrameNet. To sidestep the problem of internal ambiguity, we used the available semantic roles for all senses of the target word as features for the classifier (as described above). Solving the problem of external ambiguity was outside the scope of this work.

Some potential target words had to be ignored since their sense ambiguity was too difficult to overcome. This category includes auxiliaries such as *be* and *have*, as well as verbs such as *take* and *make*, which frequently appear as support verbs for nominal predicates.

2.3. Motivation
Although the meaning of the two sentences in a sentence pair in a parallel corpus should be roughly the same, a fundamental question is whether it is meaningful to project semantic markup of text across languages. Equivalent words in two different languages sometimes exhibit subtle but significant semantic differences. However, we believe that a transfer makes sense, since the nature of FrameNet is rather coarse-grained. Even though the words that evoke a frame may not have exact counterparts, it is probable that the frame itself has.

For the projection method to be meaningful, we must make the following assumptions:

- The complete frame ontology in the English FrameNet is meaningful in Swedish as well, and each frame has the same set of semantic roles and the same relations to other frames.
- When a target word evokes a certain frame in English, it has a counterpart in Swedish that evokes the same frame.
- Some of the FEs on the English side have counterparts with the same semantic roles on the Swedish side.

In addition, we made the (obviously simplistic) assumption that the contiguous entities we project are also contiguous on the target side. These assumptions may all be put into question. Above all, the second assumption will fail in many cases because
the translations are not literal, which means that the sentences in the pair may express slightly different information. The third assumption may be invalid if the information expressed is realized by radically different constructions, which means that an argument may belong to another predicate or change its semantic role on the Swedish side. Padó and Lapata (2005) avoid this problem by using heuristics based on a target-language FrameNet to select sentences that are close in meaning. Since we have no such resource to rely on, we are forced to accept that this problem introduces a certain amount of noise into the automatically annotated corpus.

3. Training a Swedish SRL System

Using the transferred FrameNet annotation, we trained a SRL system for Swedish text. Like most previous systems, it consists of two parts: a FE bracketer and a classifier that assigns semantic roles to FEs. Both parts are implemented as SVM classifiers trained using LIBSVM. The semantic role classifier is rather conventional and is not described in this paper. To construct the features used by the classifiers, we used the following tools:

- An HMM-based POS tagger,
- A rule-based chunker that brackets noun, verb, adjectival, prepositional, and adverb groups,
- A rule-based time expression detector,
- Two clause identifiers, of which one is rule-based and one is statistical,
- The MALT-parser dependency parser (Nivre et al., 2004), trained on a 100,000-word Swedish treebank.

We constructed shallow parse trees using the clause trees and the chunks. Dependency and shallow parse trees for a fragment of a sentence from our test corpus are shown in Figure 3. This sentence comes from the English FrameNet example corpus and has been manually translated into Swedish. In English, the fragment was the doctor was answering an emergency phone call.

### 3.1. Frame Element Bracketing Methods

We created two FE bracketing algorithms based on binary classification of chunks as starting or ending the FE. This is somewhat similar to some chunk-based FE bracketing methods described in literature. on IOB2 bracketing. However, our system still exploits the dependency parse tree during classification.

We first tried the conventional approach to the problem of FE bracketing: applying a parser to the sentence, and classifying each node in the parse tree as being an FE or not. We used a dependency parser since there is no constituent-based parser available for Swedish. This proved unsuccessful because the spans of the dependency subtrees frequently were incompatible with the spans defined by the FrameNet annotations. This was especially the case for non-verbal target words and when the head of the argument was above the target word in the dependency tree. To be usable, this approach would require some sort of transformation, possibly a conversion into a phrase-structure tree, to be applied to the dependency trees to align the spans with the FEs. Preliminary investigations were unsuccessful, and we left this to future work.

We believe that the methods we developed are more suitable in our case, since they base their decisions on several parse trees (in our case, two clause-chunk trees and one dependency tree). This redundancy is valuable because the dependency parsing model was trained on a treebank of just 100,000 words, which makes it less robust than Collins’ or Charniak’s parsers for English. Recent work in semantic role labeling has focused on combining the results of SRL systems based on different types of syntax. Still, all systems exploiting recursive parse trees are based on binary classification of nodes as being an argument or not. The training sets used to train the final classifiers consisted of one million training instances for the start classifier, 500,000 for the end classifier, and 272,000 for the role classifier. The features used by the classifiers are described in Subsection 3.2., and the performance of the two FE bracketing algorithms compared in Subsection 4.2.

#### 3.1.1. Greedy start-end

The first FE bracketing algorithm, the greedy start-end method, proceeds through the sequence of chunks in one pass from left to right. For each chunk opening bracket, a binary classifier decides if an FE starts there or not. Similarly, another binary classifier tests chunk end brackets for ends of FEs. To ensure compliance to the FrameNet annotation standard (bracket matching, and no FE crossing the target word), the algorithm inserts additional end brackets where appropriate. Pseudocode is given in Algorithm 1.

Figure 4 shows an example of this algorithm, applied to the
example fragment. The small brackets correspond to chunk boundaries, and the large brackets to FE boundaries that the algorithm inserts. In the example, the algorithm inserts an end bracket after the word doktorn ‘the doctor’, since no end bracket was found before the target word svarade ‘was answering’.

![Figure 4: Illustration of the greedy start-end method.](image)

**3.1.2. Globally optimized start-end**

The second algorithm, the globally optimized start-end method, maximizes a global probability score over each sentence. For each chunk opening and closing bracket, probability models assign the probability of an FE starting (or ending, respectively) at that chunk. The probabilities are estimated using the built-in sigmoid fitting methods of LIBSVM. Making the somewhat unrealistic assumption of independence of the brackets, the global probability score to maximize is defined as the product of all start and end probabilities. We added a set of constraints to ensure that the segmentation conforms to the FrameNet annotation standard. The constrained optimization problem is then solved using the JaCoP finite domain constraint solver (Kuchcinski, 2003). We believe that an n-best beam search method would produce similar results. The pseudocode for the method can be seen in Algorithm 2. The definitions of the predicates no-nesting and no-crossing, which should be obvious, are omitted.

Figure 5 shows an example of the globally optimized start-end method. In the example, the global probability score is maximized by a bracketing that is illegal because the FE starting at doktorn is not closed before the target (0.8 · 0.4 · 0.6 · 0.7 · 0.8 · 0.7 = 0.075).

![Figure 5: Illustration of the globally optimized start-end method.](image)

### 3.2. Features Used by the Classifiers

Table 1 summarizes the features sets used by the greedy start-end (GSE), optimized start-end (OSE), and semantic role classification (SRC).

**3.2.1. Conventional Features**

Some of the features we use are well-known from literature. Most of them have been used by almost every system since the first well-known description (Gildea and Jurafsky, 2002). These features are used by all classifiers:

- **Target word (predicate) lemma and POS**
- **Voice** (when the target word is a verb)
- **Position** (before or after the target)
- **Head word and POS**

---

**Table 1: Features used by the classifiers.**

| Feature Type | GSE | OSE | SRC |
|--------------|-----|-----|-----|
| Target lemma | +   | +   | +   |
| Target POS   | +   | +   | +   |
| Voice        | +   | +   | +   |
| Allowed role labels | +   | +   | +   |
| Position     | +   | +   | +   |
| Head word (HW) | +   | +   | +   |
| Head POS     | +   | +   | +   |
| Phrase/chunk type (PT) | +   | +   | +   |
| HW/POS/PT, ±2 chunk window | +   | +   | +   |
| Dep-tree & shallow path — target | +   | +   | +   |
| Starting paths — target | +   | +   | +   |
| Ending paths — target | +   | +   | +   |
| Path — start  | +   | -   | -   |
• Phrase or chunk type

In addition, all classifiers use the set of allowed semantic role labels as a set of boolean features. This is needed to constrain the output to a label that is allowed by FrameNet for the current frame. In addition, this feature has proven useful for the FE bracketing classifiers to distinguish between event-type and object-type frames. For event-type frames, dependencies are often long-distance, while for object-type frames, they are typically restricted to chunks very near the target word. The part of speech of the target word alone is not enough to distinguish these two classes, since many nouns belong to event-type frames.

For the phrase/chunk type feature, we use slightly different values for the bracketing case and the role assignment case: for bracketing, the value of this feature is simply the type of the current chunk; for classification, it is the type of the largest included chunk or clause that starts at the leftmost token of the FE. For prepositional phrases, the preposition is attached to the phrase type (for example, the second FE in token of the FE). For bracketing, the value of this feature is simply the type of the current chunk; for classification, it is the type of the largest included chunk or clause that starts at the leftmost token of the FE. For prepositional phrases, the preposition is attached to the phrase type (for example, the second FE in the example fragment starts with the word på ’at/on’, which causes the value of the phrase type feature to be PP-på).

3.2.2. Chunk Context Features

Similarly to some chunk-based argument bracketers, the start-end methods use the head word, head POS, and chunk type of chunks in a window of size 2 on both sides of the current chunk to classify it as being start or end of an FE.

3.2.3. Parse Tree Path Features

Parse tree path features have been shown to be very important for argument bracketing in several studies. All classifiers used here use a set of such features:

• Dependency tree path from the head to the target word.
  In the example text, the first chunk (consisting of the word doktorn) has the value SUB↑ for this feature. This means that to go from the head of the chunk to the target in the dependency graph (Figure 3), you traverse a SUB (subject) link upwards. Similarly, the last chunk (ett larmsamtal) has the value PR-↓ADV↑.

• Shallow path from the chunk containing the head to the target word.
  For the same chunks as above, these values are both NG_nom↑-Clause↓-VG_fin, which means that to traverse the shallow parse tree (Figure 3) from the chunk to the target, you start with a NG_nom node, go upwards to a Clause node, and finally down to the VG_fin node.

The start-end classifiers additionally use the full set of paths (dependency and shallow paths) to the target word from each node starting (or ending, respectively) at the current chunk, and the greedy end classifier also uses the path from the current chunk to the start chunk.

4. Evaluation of the System

4.1. Evaluation Corpus

To evaluate the system, we manually translated 150 sentences from the FrameNet example corpus. These sentences were selected randomly from the English development set. Some sentences were removed, typically because we found the annotation dubious or the meaning of the sentence difficult to comprehend precisely. The translation was mostly straightforward. Because of the extensive use of compounding in Swedish, some frame elements were merged with target words.

4.2. Comparison of FE Bracketing Methods

We compared the performance of the two methods for FE bracketing on the test set. Because of limited time, we used smaller training sets than for the full evaluation below (100,000 training instances for all classifiers). Table 2 shows the result of this comparison.

|               | Greedy | Optimized |
|---------------|--------|-----------|
| Precision     | 0.70   | 0.76      |
| Recall        | 0.50   | 0.44      |
| $F_{\beta=1}$ | 0.58   | 0.55      |

Table 2: Comparison of FE bracketing methods.

As we can see from the Table 2, the globally optimized start-end method increased the precision somewhat, but decreased the recall and made the overall F-measure lower. We therefore used the greedy start-end method for our final evaluation that is described in the next section.

4.3. Final System Performance

We applied the Swedish semantic role labeler to the translated sentences and evaluated the result. We used the conventional experimental setting where the frame and the target word were given in advance. The results, with approximate 95% confidence intervals included, are presented in Table 3. The figures are precision and recall for the full task, classification accuracy of pre-segmented arguments, precision and recall for the bracketing task, full task precision and recall using the Senseval-3 scoring metrics, and finally the proportion of full sentences whose FEs were correctly bracketed and classified. The Senseval-3 method uses a more lenient scoring scheme that counts a FE as correctly identified if it overlaps with the gold standard FE and has the correct label. Although the strict measures are more interesting, we include these figures for comparison with the systems participating in the Senseval-3 Restricted task (Litkowski, 2004).

We include baseline scores for the argument bracketing and classification tasks, respectively. The bracketing baseline method considers non-punctuation subtrees dependent of the target word. When the target word is a verb, the baseline puts FE brackets around the words included in each of these subtrees. When the target is a noun, we also bracket the target word token itself, and when it is an adjective, we additionally bracket its parent token. As a baseline for the argument classification task, every argument is assigned the most frequent semantic role in the frame. As can be seen from the table, all scores except the argument bracketing recall are well above the baselines.

1 This is possible because MALTPARSER produces projective trees, i.e. the words in each subtree form a contiguous substring of the sentence.
Although the performance figures are better than the baselines, they are still lower than for most English systems (although higher than some of the systems at Senseval-3). We believe that the main reason for the performance is the quality of the data that were used to train the system, since the results are consistent with the hypothesis that the quality of the transferred data was roughly equal to the performance of the English system multiplied by the figures for the transfer method (Johansson and Nugues, 2005). In that experiment, the transfer method had a precision of 0.84, a recall of 0.81, and an F-measure of 0.82. If we assume that the transfer method to be useful in a fully automatic setting. Apart from the noisy training set, probable reasons for this include the lower robustness of the Swedish parsers compared to those available for English. In addition, we have noticed that the European Parliament corpus is somewhat biased. For instance, a very large proportion of the target words evoke the STATEMENT or DISCUSSION frames, but there are very few instances of the BEING_WET and MAKING_FACES frames. While training, we tried to balance the selection somewhat, but applying the projection methods on other type of parallel corpora (such as novels available in both languages) may produce a better training corpus.

5. Conclusion

We have described the design and implementation of a Swedish FrameNet-based SRL system that was trained using a corpus that was annotated using cross-language transfer from English to Swedish. With no manual effort except for translating sentences for evaluation, we were able to reach promising results. To our knowledge, the system is the first SRL system for Swedish in literature. We believe that the methods described could be applied to any language, as long as there exists a parallel corpus where one of the languages is English. However, the relatively close relationship between English and Swedish probably made the task comparatively easy in our case.

Table 3: Results on the Swedish test set with approximate 95% confidence intervals.

|                          | Precision (Strict scoring method) | Recall    | Argument Classification Accuracy |
|---------------------------|------------------------------------|-----------|----------------------------------|
|                          | 0.67 ± 0.064                       | 0.47 ± 0.057 | 0.75 ± 0.050                     |
|                          |                                    |           | Baseline Recall                   |
|                          | 0.41 ± 0.056                       |           |                                    |
|                          |                                    |           | Argument Bracketing Precision     |
|                          | 0.80 ± 0.055                       | 0.50 ± 0.055 | 0.57 ± 0.057                     |
|                          |                                    |           | Baseline Recall                   |
|                          | 0.55 ± 0.057                       |           |                                    |
|                          |                                    |           | Precision (Senseval-3 scoring method) |
|                          | 0.77 ± 0.057                       | 0.75 ± 0.039 | 0.55 ± 0.057                     |
|                          |                                    |           | Overlap                           |
|                          | 0.75 ± 0.057                       |           |                                    |
|                          |                                    |           | Recall                            |
|                          | 0.55 ± 0.057                       |           |                                    |
|                          |                                    |           | Complete Sentence Accuracy         |
|                          | 0.29 ± 0.073                       |           |                                    |
