ABSTRACT

Introduction: The loss of mitochondrial function and content have been implicated in sarcopenia although they have been little studied in the very old, the group in which sarcopenia is most common. In this pilot study, our aim was to determine if mitochondrial respiratory chain function and content are preserved among healthy 85-year-olds.

Methods: We recruited 19 participants (11 female) through their general practitioner and assessed their medical history, functional status and self-reported physical activity. We identified sarcopenia using grip strength, Timed Up-and-Go and bioimpedance analysis. We assessed mitochondrial respiratory chain function using phosphorous magnetic resonance spectroscopy, estimating $\frac{1}{2}$ PCr, the recovery half-time of phosphocreatine in the calf muscles following a bout of aerobic exercise. We performed a biopsy of the vastus lateralis muscle and assessed mitochondrial respiratory chain content by measuring levels of subunits of complex I and IV of the respiratory chain enzymes, expressed as $Z$-scores relative to that in young controls.

Results: Participants had a median (IQR) of 2 (1,3) long-term conditions, reported regular aerobic physical activity, and one participant (5.3%) had sarcopenia. Sixteen participants completed the magnetic resonance protocol and the mean (SD) $\frac{1}{2}$ PCr of 35.6 (11.3) seconds was in keeping with preserved mitochondrial function. Seven participants underwent muscle biopsy and the mean $Z$-scores were $-0.7$ (0.7) and $-0.2$ (0.4) for complexes I and IV, respectively, suggesting preserved content of mitochondrial respiratory chain enzymes.

Conclusion: Muscle mitochondrial respiratory chain function and content are preserved in a sample of active, well-functioning 85-year-olds, among whom sarcopenia was uncommon. The results from this study will help inform future work examining the association between muscle mitochondrial deficiency and sarcopenia.

1. Introduction

Impairments in skeletal muscle mitochondrial function and content have been implicated in the development of sarcopenia, the age-related loss of muscle mass and performance (Brierley et al., 1996; St-Jean-Pelletier et al., 2017; Joseph et al., 2012). The assessment of skeletal muscle mitochondria presents challenges. Assessment of content, such as staining for cytochrome oxidase, requires the collection of muscle tissue, as do in vitro measures of function such as respirometry of isolated mitochondria (Hepple, 2014). In vivo measurement of function is possible using phosphorous magnetic resonance spectroscopy ($^{31}$P-MRS), requiring participants to undertake controlled exercise sufficient to deplete muscle reserves of phosphocreatine (Hollingsworth et al., 2008).

As expected for an age-related condition, sarcopenia is most common among the very old (Cruz-Jentoft et al., 2014), with a prevalence of 21% in a sample of 85-year-olds (Dodds et al., 2017). There have been few studies of mitochondrial function and content in this age...
group, with relevant studies typically having a mean age below 85
(Coen et al., 2013; Choi et al., 2016; Spendiff et al., 2016; Rygiel et al.,
2017; Distefano et al., 2017). The opportunity to collect muscle samples
during hip fracture surgery has been used to investigate whether im-
paired mitochondrial homeostasis is associated with sarcopenia among
the very old (Marzetti et al., 2016). Older patients with hip fracture are
recognised to have not only high levels of sarcopenia but also disability
and multimorbidity (Di Monaco et al., 2011; Krishnan et al., 2014); in
this setting, the influences of ageing per se and those of acute illness and
overall frailty may be difficult to disentangle.

A complementary approach is to study community-dwelling very
old individuals, including those with few medical and functional prob-
lems, who may provide important insights into factors that promote
healthy ageing (Ferrucci, 2008). We therefore undertook a pilot study
in which we assessed the feasibility of recruiting community-dwelling
85-year-old people to attend for detailed phenotyping including
31P-MRS and muscle biopsy. The aim of the present study was to determine
if skeletal muscle mitochondrial respiratory chain function and content
are preserved among healthy 85-year-olds.

2. Methods

2.1. Participants

We recruited participants aged 85 years, born in 1931, who were
registered with a general practice within the North East & North
Cumbria Clinical Research Network, England. We excluded those with a
cardiac pacemaker or any other metallic or programmable device
registered with a general practice within the North East & North

2.2. Identification of sarcopenia

We measured grip strength (kg) with a Jamar handheld hydraulic
dynamometer (Promedics, UK) using three trials in both hands fol-
lowing a standard protocol (Roberts et al., 2011) and using the max-
imum value obtained for analyses. Participants completed the Timed
Up-and-Go (TUG) test: a stopwatch was used to measure the time taken
to get up from a chair and walk as quickly and safely as possible up to
and around a marker placed 3 m away, walk back to the chair and sit
back down. We converted this time to an estimate of gait speed (m/s)
using the formula (6 / (TUG time)) + 1.62 (Cooper et al., 2011; Cooper
et al., 2015). We measured total body weight (kg) and estimated appen-
dicular lean mass (kg) using a Tanita MC-780MA body composition
analyser (Tanita Corporation, Arlington Heights, IL.). We estimated
height based on demi-span, measured twice to the nearest millimetre.
We calculated skeletal muscle index (SMI) (kg/m²) from appendicular
lean mass divided by height-squared. We applied the European Working
Group sarcopenia definition to our results, using recognised
cut-points for grip strength of ≤ 30 kg in men and < 20 kg in women,
for gait speed of ≤ 0.8 m/s and for SMI of < 7.26 kg/m² in men and
< 5.45 kg/m² in women (Cruz-Jentoft et al., 2010). We considered
participants with weak grip and/or slow gait speed, in combination
with low SMI, to have sarcopenia.

2.3. Phosphorous magnetic resonance spectroscopy

Participants attended for 31P-MRS scanning and were requested to
perform a low-intensity plantar flexion exercise in the scanner with
incremental loading, until the phosphocreatine in the gastrocnemius
and soleus muscles was depleted by approximately 50%. Measurements
were taken every 10 s during exercise and recovery. We fitted an ex-
ponential recovery curve to the area under the phosphocreatine peak
from which we modelled the time taken, τ₁/₂ PCr (seconds), for re-
covery halfway to baseline, as a measure of mitochondrial oxidative
function, with shorter times implying higher function (Hollingsworth
et al., 2008) (Fig. 1).

2.4. Muscle biopsy

We obtained biopsy of the vastus lateralis muscle under local an-
aesthesia from seven participants using a Weil Blakesley conchotome.
The samples were snap frozen in isopentane cooled in liquid nitrogen.
We telephone participants the following day to check their wellbeing
and visited them at home one week after their biopsy to check the
wound had healed and that there were no signs of infection present.
We also enquired about any pain at the site, rated on a scale of 0 (no pain) –
10 (worst pain).

2.5. Quadruple immunofluorescence

Two 10 μm sections from each biopsy were used for the quadruple
immunofluorescence with antibodies to laminin, NDUFB8 (subunit of
complex I), MTCOI (subunit of complex IV) and porin, as described
previously (Rygiel et al., 2017; Rocha et al., 2015) (Fig. 1). Control
samples were biopsies obtained from five younger patients undergoing
orthopaedic surgery (see Supplementary Table 1 for full details). The
control and participant sections were reacted the same day with the
same batch of antibody and identical concentrations. All exposure times
were set and maintained throughout the imaging.

The immunofluorescence data from the fibres in the control samples
were used to produce linear regression models for the relationships
between levels of complex I and porin, and between complex IV and
porin. The regression findings were then used to predict the expected
levels of complex I and IV per fibre among study participants based on
the fibres’ measured porin levels. The measured values in complex I and
IV were then expressed as Z-scores (the number of standard deviations
the measured values were above that predicted by the linear regression
models). We classified fibres with Z ≥ −3 (so measured values no
lower than 3 standard deviations below that predicted from the re-
relationships seen in young controls) as positive.
Fig. 1. Assessment of mitochondrial function and content.
Sample results for mitochondrial function and content (NB two different participants are shown). A. Exponential recovery curve for phosphocreatine following exercise. $\tau_{1/2}$ PCr for participant shown is 36.6 s. B. Quadruple immunofluorescence. Mean Z-scores from participant shown of 0.6 for complex IV (MTCOI) and 0.1 for complex I (NDUFB8).
3. Results

Table 1 shows the characteristics of the 19 participants recruited to the study. They had a median of two diseases and high levels of self-reported physical function and general health, especially among the women in the sample and when compared to normative data for the same age group (Bowling et al., 1999). They regularly engaged in aerobic physical activity with a mean RAPA score of 4.8 (1.4). Their mean results for the components of sarcopenia were either above the relevant cut-points (gait speed, SMI) or just below (grip strength); as such only one participant had sarcopenia according to the EWGSOP definition.

3.1. Mitochondrial function assessed using magnetic resonance spectroscopy

We collected valid 31P-MRS data in 16 participants (one was unable to attend, one declined the scan and in one participant their phosphocreatine did not deplete adequately during exercise). The mean \( \tau_{1/2} \) PCr was 35.6 (11.3) seconds, in keeping with preserved mitochondrial oxidative capacity (Hollingsworth et al., 2008). The scan procedure was well tolerated by all participants who undertook the test.

3.2. Mitochondrial content assessed using quadruple immunofluorescence

Seven participants had a muscle biopsy collected. Reasons for non-participation included the presence of visible veins over the planned biopsy site (\( n = 5 \)), use of medications that could increase risk of bleeding or poor wound-healing (\( n = 3 \)) and participants being unavailable (\( n = 1 \)) or unwilling (\( n = 3 \)) to have biopsy. We saw no differences in the baseline characteristics (as shown in Table 1) between those participants who did and those who did not have muscle biopsy.

There was little evidence of deficiency in men or women of either of the two mitochondrial respiratory chain complexes tested, as shown in Table 2. There were no complications noted at the follow-up home visit and none of the seven participants reported any pain at the biopsy site.

### Table 1

Sample characteristics.

| Characteristic | Men (n = 8) | Women (n = 11) | All (n = 19) |
|----------------|------------|---------------|-------------|
| Age at interview (years) | 84.9 (0.3) | 85.0 (0.3) | 85.0 (0.3) |
| Disease count [median (IQR)] | 3 (2.3) | 1 (1.3) | 2 (1.3) |
| No. of prescribed medications [median (IQR)] | 7 (3.14) | 5 (4.6) | 6 (3.11) |
| Geriatric depression score | 2 (1.2) | 1 (0.2) | 1 (0, 2) |
| Mini-mental state examination score | 29 (29,30) | 30 (29,30) | 29 (29,30) |
| Number of ADLs with difficulty/ help needed | 2 (0.3) | 0 (0.2) | 1 (0, 2) |
| SF-36 self-reported physical function \((0–100)^{\dagger}\) | 62.4 (23.4) | 79.4 (16.5) | 73.1 (20.6) |
| SF-36 self-reported general health \((0–100)^{\dagger}\) | 70 (9.6) | 79.6 (10.1) | 75.5 (10.8) |
| RAPA aerobic activity score \((1–7)^{\dagger}\) | 4.6 (1.6) | 5 (1.3) | 4.8 (1.4) |
| RAPA strength and flexibility score \((0–3)^{\dagger}\) | 0.9 (1.0) | 0.6 (0.8) | 0.7 (0.9) |
| Grip strength (kg) | 29.9 (6.2) | 19.1 (6.1) | N/A |
| Gait speed (m/s) | 0.9 (0.4) | 1.1 (0.3) | 1.0 (0.3) |
| BMI (kg/m²) | 27.6 (3.1) | 24.4 (4.2) | 25.7 (4.0) |
| SMI (kg/m²) | 8.1 (0.8) | 6.4 (1.0) | N/A |
| EWGSOP sarcopenia \([n (%)]\) | 1 (12.5%) | 0 (0%) | 1 (5.3%) |

### Table 2

Mitochondrial function and content.

| Characteristic | Men | Women | All |
|----------------|-----|-------|-----|
| Phosphorous magnetic resonance spectroscopy | n = 6 | n = 10 | n = 16 |
| Phosphocreatine recovery rate, \( \tau_{1/2} \) PCr (s) | 33.1 (8.6) | 37.0 (12.9) | 35.6 (11.3) |
| Quadruple immunofluorescence | n = 3 | n = 4 | n = 7 |
| Complex I Mean fibre Z-score | −0.5 (1.1) | −0.7 (0.4) | −0.7 (0.7) |
| Proportion of positive fibres \((Z ≥ −3) (%)\) | 98.9 (1.4) | 98.6 (0.2) | 98.7 (0.9) |
| Complex IV Mean fibre Z-score | 0.0 (0.4) | −0.3 (0.5) | −0.2 (0.4) |
| Proportion of positive fibres \((Z > −3) (%)\) | 99.4 (0.4) | 98.8 (0.3) | 99.1 (0.5) |

### 4. Discussion

In this pilot study we carried out an initial investigation of skeletal muscle mitochondrial respiratory chain function and content in an active and healthy sample of 85-year-olds, among whom sarcopenia was uncommon. We found that phosphocreatine recovery time from 31P-MRS (in 17 participants) and levels of subunits of complexes I and IV from quadruple immunofluorescence (in 7 participants) were preserved. Both assessments were well tolerated.

Reduction in content and changes to the functions of skeletal muscle mitochondria including reduced respiratory chain function, sensitisation to permeability transition and impaired quality control may contribute to the development of sarcopenia (Hepple, 2014; Marzetti et al., 2013). In addition to those used in the present study, a range of techniques have been used to investigate these changes. For content these include histochemistry of enzymes such as cytochrome c oxidase (Brierley et al., 1996) and mtDNA copy number (Short et al., 2005). For functions they include ex-vivo measurement of respiration in permeabilized myofibres (Spendiff et al., 2016; Distefano et al., 2017) and Western immunoblotting of proteins regulating quality control processes (Marzetti et al., 2016).

There is debate on the extent to which age-related changes in mitochondria represent a primary organelle defect or occur secondary to concomitant reductions in physical activity and cardiorespiratory fitness. Several studies have compared the mitochondrial function and content in young active individuals to that seen in older active and older sedentary groups (St-Jean-Pelletier et al., 2017; Spendiff et al., 2016; Safdar et al., 2010; Distefano et al., 2018) and to that seen in sedentary individuals across a range of ages (Distefano et al., 2017). They have shown that increased habitual physical activity appears to attenuate age-related declines in mitochondrial function and content, with evidence from exercise intervention studies supporting this (Broskey et al., 2014; Lundby and Jacobs, 2016). Therefore, the regular aerobic activity undertaken by participants in our study may have contributed to the preserved mitochondrial function and content.

We are not aware of other data for 31P-MRS of the gastrocnemius and soleus muscles in the very old. Taylor et al. previously reported a similar mean \( \tau_{1/2} \) PCr of 32 s in these muscles following exercise in a sample of six healthy men and women aged 70–83 years (Taylor et al., 1997). Two previous studies have reported 31P-MRS data for the quadriceps from three samples with mean ages between 72 and 79 years.
(Santanasto et al., 2016; Zane et al., 2017), expressed as the recovery rate constant, $k_{PCr}$. If we assume that the two muscle sites are comparable and convert $k_{PCr}$ to $\tau_{1/2}$ PCR (using the formula $\tau_{1/2}$ PCR = $-\ln (0.5) / k_{PCr}$), then their summary values are again similar to our own: ranging from 33.0 to 36.5 s. It is likely that we do not see abnormally long values in our older sample as they regularly engage in aerobic physical activity. This has been shown to have marked benefits for function assessed by 31P-MRS of the quadriceps in a sample of young men (Yoshida, 2002), and more recently when comparing older active and sedentary individuals at mean ages 68 and 71, respectively (Distefano et al., 2018).

We also saw largely positive fibres on quadruple immunofluorescence, with mean Z-scores of the complex I and IV subunits in the positive range ($Z > -3$), as we previously reported in a sample of community-dwelling older men at mean age 73 (Rygiel et al., 2017). The high level of physical activity undertaken by our participants may have attenuated the age-related decline in mitochondrial respiratory enzyme content (St-Jean-Pelletier et al., 2017; Distefano et al., 2018; Brierley et al., 1997).

We found that it was feasible to undertake 31P-MRS including exercise of the calf muscles in a healthy sample of 85-year-olds and that the procedure was well tolerated. The majority of participants were also willing to undergo biopsy and those who did reported little discomfort following the procedure, in keeping with existing research (Patel et al., 2011; Baczynska et al., 2017). We exercised caution when deciding to proceed with biopsy, for example excluding participants with visible veins around the biopsy site. Understanding more about the acceptability and feasibility of muscle biopsy in the very old would allow cellular and molecular mechanistic studies in this age group to flourish.

This study had several strengths. We successfully recruited a sample of healthy 85-year-old people for detailed phenotyping related to skeletal muscle. We carried out an initial home visit, giving participants opportunity to meet a member of the study team and discuss what the study involved; this has previously been linked to engagement with intensive assessments such as muscle biopsy (Baczynska et al., 2017).

Limitations of this study include the fact that we assessed physical activity using a questionnaire; an objective measurement would have given us useful additional information regarding the intensity and patterns of activity. We did not attempt muscle biopsy in around two-thirds of participants, mainly due to skin changes or medication history. Our sample was also biased towards healthier and more active participants, among whom sarcopenia and other conditions were less common than average for this age group (Dodds et al., 2017; Collerton et al., 2016). This may in part reflect the study’s exclusion criteria: for example, those taking anticoagulant drugs are more likely to have cardiovascular disease than the general population. The small sample size of our study prevented us from examining associations between mitochondrial function/content and the components of sarcopenia. The small sample sizes and variability of the measures we report also suggest that the mean values we show in Table 2 may well not be representative of the underlying population.

In conclusion, we found that skeletal muscle respiratory chain function, assessed using 31P-MRS, and the content of two respiratory chain subunits in muscle biopsy samples were preserved in a healthy, active sample of 85-year-old men and women. This is likely to reflect the fact that our sample reported regularly engaging in aerobic exercise. These results will help to inform future studies in this age group, including in those with lower activity levels and higher levels of sarcopenia than in this pilot study.

Declarations

Funding

This study was funded by a Medical Research Council Confidence in Concept grant to AAS.

The research was supported by the NIHR Newcastle Biomedical Research Centre awarded to the Newcastle upon Tyne Hospitals NHS Foundation Trust and Newcastle University, Wellcome Centre for Mitochondrial Research (203105/Z/16/Z), the Medical Research Council (MRC) Centre for Translational Research in Neuromuscular Disease, Newcastle University Centre for Ageing and Vitality (supported by the Biotechnology and Biological Sciences Research Council and MRC) and Mitochondrial Disease Patient Cohort (UK) (G0800674). The views expressed are those of the author(s) and not necessarily those of the NHS, the NIHR or the Department of Health.
