Urotensin II-induced signaling involved in proliferation of vascular smooth muscle cells

Myriam Iglewski

Abstract: The urotensin II receptor, bound by the ligand urotensin II, generates second messengers, ie, inositol triphosphate and diacylglycerol, which stimulate the subsequent release of calcium (Ca\textsuperscript{2+}) in vascular smooth muscle cells. Ca\textsuperscript{2+} influx leads to the activation of Ca\textsuperscript{2+}-dependent kinases (CaMK) via calmodulin binding, resulting in cellular proliferation. We hypothesize that urotensin II signaling in pulmonary arterial vascular smooth muscle cells (Pac1) and primary aortic vascular smooth muscle cells (PAVSMC) results in phosphorylation of Ca\textsuperscript{2+}/calmodulin-dependent kinases leading to cellular proliferation. Exposure of Pac1 cultures to urotensin II increased intracellular Ca\textsuperscript{2+}, subsequently activating Ca\textsuperscript{2+}/calmodulin-dependent kinase kinase (CaMKK), and Ca\textsuperscript{2+}/calmodulin-dependent kinase Type I (CaMKI), extracellular signal-regulated kinase (ERK 1/2), and protein kinase D. Treatment of Pac1 and PAVSMC with urotensin II increased proliferation as measured by \textsuperscript{3}H-thymidine uptake. The urotensin II-induced increase in \textsuperscript{3}H-thymidine incorporation was inhibited by a CaMKK inhibitor. Taken together, our results demonstrate that urotensin II stimulation of smooth muscle cells leads to a Ca\textsuperscript{2+}/calmodulin-dependent kinase-mediated increase in cellular proliferation.

Keywords: urotensin II receptor, CaMKI, hypertrophy, CaMKK, protein kinase D

Introduction
Hypertrophy, inflammation, and proliferation of vascular cells are major contributors to diseases such as atherosclerosis, arteriosclerosis, and hypertension.\textsuperscript{1} The combined effects of these major contributors are increases in cell size, migration of immune cells, and abnormal cell growth in affected regions of the vessel.\textsuperscript{2} Changes in vessel structure due to vascular remodeling result in narrowing of the vessel wall and arterial stiffness.\textsuperscript{2} Contraction and relaxation of vascular smooth muscle cells are regulated by biologically active mediators which are synthesized and secreted to modulate vascular tone.\textsuperscript{1} Many of these same mediators also play a pathologic role, such as urotensin II, which can induce abnormal cellular proliferation during disease-related vascular remodeling.\textsuperscript{1}

Urotensin II is similar to somatostatin in both structure and function. Urotensin II is an undecapeptide cleaved from a precursor molecule that stimulates potent vasoconstriction and vascular smooth muscle cell proliferation.\textsuperscript{3,4} Under nonpathologic conditions, urotensin II influences vascular smooth muscle contraction.\textsuperscript{5} However, under pathologic conditions, urotensin II promotes cellular migration, and modulates large blood vessels, as shown in studies conducted in human aortic smooth muscle cells.\textsuperscript{6}

Urotensin II is recognized by the orphan G-protein coupled GPR-14, now identified as the urotensin II receptor, resulting in generation of the second messengers,
in phosphorlylation in various cell types. These second messengers trigger the release of Ca\(^{2+}\) from the sarcoplasmic reticulum. The urotensin II receptor is expressed in many tissues, including vascular smooth muscle, although the precise mechanisms activated downstream of the urotensin II receptor in vascular smooth muscle cells are largely unknown. Studies of other Gq-coupled receptors have shown that stimulation induces intracellular Ca\(^{2+}\) influx and binding of Ca\(^{2+}\) to calmodulin. Activated calmodulin subsequently binds to and stimulates calmodulin-dependent kinases (CaMK), such as Ca\(^{2+}\)/calmodulin-dependent kinase kinase (CaMKK). Activation of CaMK members can lead to Ca\(^{2+}\)-dependent activation of other protein kinases, such as extracellular signal-regulated kinase (ERK) and protein kinase D (PKD).

ERK phosphorylation is required for proliferation of various cell types and cell lines. Vascular remodeling, hypertrophy, and proliferative responses are believed to be the result of urotensin II receptor overstimulation. Studies in thoracic aortic cells demonstrated that urotensin II receptor signaling stimulates the phosphorylation of ERK. In addition to ERK activation, intracellular Ca\(^{2+}\) influx can also modulate the activity of PKD. Vasoactive agents, such as endothelin-1, that bind Gq-coupled receptors, have been demonstrated to mediating PKD phosphorylation in various cell types. Here, we show that urotensin II induces intracellular Ca\(^{2+}\) release which stimulates CaMKI phosphorylation in Pac1. Moreover, we demonstrate that urotensin II receptor stimulation leads to CaMK-dependent phosphorylation of ERK and PKD. We go on to reveal that the acute application of urotensin II results in cellular proliferation, which can be blocked by inhibition of CaMKK. Consistent with our hypothesis, we have found that urotensin II-induced CaMKI, ERK, and PKD phosphorylation are also blocked by inhibition of CaMKK in vascular smooth muscle cells. These observations potentially indicate that urotensin II-induced signaling triggers proliferation and may contribute to hypertrophic pathologic conditions.

**Materials and methods**

**Cell culture**

Rat pulmonary arterial smooth muscle cells (Pac1) were cultured according to the method described by Rothman et al. In brief, rat Pac1 were cultured in medium 199 (Invitrogen, Carlsbad, CA) supplemented with 10% fetal bovine serum with gentamicin (Fisher Scientific, Pittsburgh, PA). The cells were carried only through passages 3–15.

**Primary aortic smooth muscle cells**

Rat aortas were isolated from three-month-old Sprague-Dawley rats according to an established protocol. The aortas were incubated for five minutes in 10% fetal bovine serum and 199 medium, then incubated at 37°C for 30 minutes in Hanks Balanced Salt Solution (Invitrogen-GIBCO, Carlsbad, CA) with 70 U/mL of collagenase (Millipore-Worthington Biochemical Company, Billerica, MA). Adventitias were stripped from the aortic tissue with watchmaker forceps and discarded. Aortas were digested in Hanks Balanced Salt Solution with collagenase 70 U/mL and elastase 40 U/mL (Sigma Aldrich, St Louis, MO). Aortas were gently agitated at 37°C for 90 minutes. The aortic solution was passed through a strainer with a 70 µm pore size, and centrifuged at 900 rpm for five minutes. Cellular suspensions were dispersed by pipetting the suspensions up and down. Cells were then plated in six-well plates containing 10% fetal bovine serum in 199 medium.

**Calcium imaging**

Pac1 (1 × 105 cells/mL) were grown on coverslips at 70%–80% confluency, and then bathed in Hanks Balanced Salt Solution (containing NaCl 0.137 M, KCl 5.4 mM, Na\(_2\)PO\(_4\) 0.25 mM, KH\(_2\)PO\(_4\) 0.44 mM, MgSO\(_4\) 1.0 mM, NaHCO\(_3\) 4.2 mM) with and without Ca\(^{2+}\) for measuring intracellular Ca\(^{2+}\). Detection of intracellular Ca\(^{2+}\) was quantified using a ratiometric technique recognized by Fura-2-AM (Invitrogen) involving excitation at 340 nm and 380 nm with emission at 510 nm according to Prasanne et al. A Nikon Diaphot microscope using Metafluor software (Universal Imaging, West Chester, PA) was used to measure intracellular Ca\(^{2+}\). Concentration (nM) of intracellular Ca\(^{2+}\) was calculated using the Grynkeiwicz equation. Ethylenediamine tetraacetic acid 0.5 µM, a membrane-impermeable chemical chelating agent that binds Ca\(^{2+}\), was used to reverse the elevated levels of Ca\(^{2+}\). BAPTA-AM (1, 2-bis(2-amino phenoxo)-ethane-N,N,N’,N’-tetra-acetic acid) 10 µM (Invitrogen) was also used as a Ca\(^{2+}\) chemical chelating agent. BAPTA-AM, a membrane-permeable compound, also reverses the elevated levels of intracellular Ca\(^{2+}\).

**Immunostaining**

Pac1 and PAVSMC were cultured (1 × 105 cells/mL) on glass coverslips and washed twice with phosphate-buffered solution and fixed for 15 minutes with 4% paraformaldehyde at room temperature. Cells were blocked for one hour in blocking solution (3.0% bovine serum albumin in phosphate-buffered solution), and then incubated for...
one hour in primary antibody smooth muscle cell-specific antimonyin IgG (Biomedical Technologies Incorporated, Stoughton, MA) diluted 1:200 or anti-GPR14R (antibody for the urotensin II receptor, Alpha Diagnostic International Inc., Woodlake Center, TX) antibody 1:200 with blocking solution. The secondary fluorescent labeling was incubated with cells using 1:500 Alexa 488 goat/antirabbit (Molecular Probes- Invitrogen, Eugene, OR) in blocking solution. The cells were washed three times with phosphate-buffered solution. Coverslips were mounted on slides with Pro-Long Gold Anti-Fade and DAPI (Invitrogen). A DP70 Olympus digital camera and AX70 fluorescent microscope was used to visualize stained cells (40 × objective).

**3H-thymidine incorporation assay**

Pac1 and PAVSMC were seeded (8 × 104 cells/mL) in RPMI (Invitrogen) medium containing 10% fetal bovine serum. After 70% confluence, cells were washed with phosphate-buffered solution and serum starved in serum-free media to induce G1 arrest. Cells were serum-starved for 24 and 48 hours and were incubated in serum-free RPMI media or isotonic artificial CSF (ACSF, 142 mM NaCl, 5 mM KCl, 10 mM glucose, 1.3 mM Mg2+ 10 mM HEPES, and in the presence or absence of 3.1 mM Ca2+ containing 1 μCi/mL of 3H-thymidine, specific activity 48.0 Ci/mmol (GE-Healthcare Amersham, Piscataway, NJ) for four hours in the CO2 incubator at 37°C in the presence and absence of urotensin II 100 nM (Sigma Aldrich) and STO609 250 nM (Sigma Aldrich). After the four-hour incubation period, cells were washed with phosphate-buffered solution. Cells were precipitated with 15% trichloroacetic acid and incubated overnight at 4°C. Cells were then lysed with 1 Normal NaOH and were incubated for 30 minutes at room temperature. Cell lysates were transferred to tubes containing scintillation fluid for analysis using a Beckman 1539 scintillation counter. Proliferation was measured by incorporation of 3H-thymidine.

**Western blot analysis**

Pac1 were seeded at a density of 4 × 104 cells/mL and cultured until cells were 80% confluent in 100 mm3 dishes. The day prior to treatment, the cells were serum-reduced in 0.1% fetal bovine serum and 199 medium with gentamicin (Invitrogen) or 0.1% fetal bovine serum in ACSF. Twenty-four hours after serum reduction, cells were treated with 100 nM rat urotensin II (Sigma Aldrich), and 250 nM STO609, a synthetic 7-oxo-7H-benzimidazo [2,1-a]benz[de] isoquinoline-3-carboxylic acid-acetic acid peptide (Sigma Aldrich). All treatment conditions were carefully selected based on preliminary dose- and time-dependent studies. Experiments with the use of inhibitors were conducted under optimal conditions, and the concentrations were based on previous studies as referenced earlier. Inhibitors were incubated 30 minutes prior to urotensin II treatments. Dose-response and time-course investigations were conducted with urotensin II treatment. Cells were lysed using RIPA buffer (50 mM TrisHCl, 150 mM NaCl, 2 mM ethylenediamine tetraacetic acid, 1% NP-40, and 0.1% sodium dodecyl sulfate pH 7.4) and a protease inhibitor cocktail (Sigma Aldrich) containing phosphate inhibitors. Protein concentration was measured by the bicinchoninic acid method. Equal amounts of protein (20–30 μg) were loaded and electrophoresed in 10% sodium dodecyl sulfate-acrylamide gel. Proteins were transferred to PVDF membrane (Millipore, Billerica, MA). The membrane was incubated with respective phosphospecific primary antibodies at 4°C overnight and with corresponding horseradish peroxidase-conjugated secondary antibody at room temperature for one hour. After washing with 1 × phosphate-buffered solution three times at room temperature, the phosphorylation state of the proteins were detected by chemiluminescence (GE Healthcare Amersham). Phosphospecific antibodies used for the Western blots were p-ERK1/2 (Cell Signaling-9106S), p-PKD (Cell Signaling, Boston, MA) and pCaMKI (threonine 178, T Soderling Vol- lum Institute, Oregon Health Science University, Portland, OR). Loading control was determined by stripping the blot and reprobing with anti-beta actin antibody (Santa Cruz Biotech, Santa Cruz, CA). Expression of the urotensin II receptor was measured using anti-GPR14R (antibody for the urotensin II, Alpha Diagnostic International Inc., San Antonios, TX) antibody.

**Adenoviral infection**

Pac1 were seeded into six-well plates. Cells were grown in 199 medium containing 10% serum with penicillin and streptomycin. Cells were allowed to reach near confluency and were infected with the adenovirus Ad- urotensin II and Ad-GO-GFP. The adenovirus-containing (Ad-urotensin II-GFP) and the control adenovirus (Ad-GO-GFP) were both obtained from Walter Thomas (Baker Heart Research Institute, Melbourne, Australia).25 Plaque forming units (PFU) in HEK293 cells were measured to determine the viral titer, which was approximately 1.5 × 107 PFU/mL. The efficiency of infection for viral load was determined by observation of GFP fluorescence under the microscope. Virus-containing media was washed from the cells, and 10% serum-containing media was incubated for 18 hours for expression of virus.
Statistical analysis

Western blot densitometry values were normalized and evaluated relative to control. Ca\textsuperscript{2+} imaging data were presented relative to control in terms of percentage change. Densitometry, Ca\textsuperscript{2+}, and proliferation data were subjected to one-way analysis of variance (ANOVA, GraphPad-Prism, San Diego, CA) and the Newman-Keuls multiple range test was used for pairwise comparisons of the means. Statistical significance was indicated by $P \leq 0.05$.

Results

Urotensin II receptor is expressed in Pac1 and PAVSMC

To investigate urotensin II-induced signaling, we used both Pac1 and PAVSMC to verify the expression of the urotensin II receptor. Pac1 are rapidly dividing cells,\textsuperscript{11} and therefore may not accurately represent the characteristics observed in normal vascular smooth muscle cells. Thus, we incorporated the two cell types to identify the urotensin II receptor signaling mechanisms. Previous studies have identified urotensin II receptor expression in PAVSMC, but urotensin II receptor expression in Pac1 lines have not been examined.\textsuperscript{10} Western blot analysis confirms that Pac1 have higher levels of the urotensin II receptor compared with PAVSMC (Figure 1A). Immunocytostaining of both cell types with anti-urotensin II receptor antibody indicated the presence of the urotensin II receptor compared with PAVSMC (Figure 1A). Immunocytostaining of both cell types with anti-urotensin II receptor antibody indicated the presence of the urotensin II receptor in both Pac1 and PAVSMC (Figure 1B).

Urotensin II induces mobilization of Ca\textsuperscript{2+} in Pac1 and PAVSMC

It is well established that binding of urotensin II to the urotensin II receptor leads to mobilization of intracellular Ca\textsuperscript{2+}.\textsuperscript{26} We measured intracellular Ca\textsuperscript{2+} transients in urotensin II-treated Pac1 and PAVSMC using Fura-2-AM dye and digital imaging microfluorometry. Figures 2A and 2B demonstrate that urotensin II increases Ca\textsuperscript{2+} to 800 nM over 30 seconds in Pac1 (Figure 2A) and 600 nM in PAVSMC (Figure 2B). Pac1 and PAVSMC (Figure 2C) are representative images before and after urotensin II treatment. The Fura-2-AM scale,
as shown in Figure 2D, illustrates the level of intracellular Ca²⁺, demonstrating that urotensin II induces an increase in Ca²⁺. In Figure 2E we show that urotensin II-induced Ca²⁺ release does not depend on extracellular Ca²⁺. The increase in cytoplasmic Ca²⁺ in response to urotensin II is the same for cells cultured in Hanks Balanced Salt Solution media with or without Ca²⁺. Ethylenediamine tetraacetic acid (membrane-impermeable) and BAPTA-AM (membrane-permeable) served as our controls in Figure 2E. Taken as a whole, the results in Figure 2 suggest that 100 nM urotensin II causes a release of Ca²⁺ from internal stores in Pac1 and PAVSMC. Urotensin II induces phosphorylation of CaMKI, ERK, and PKD in Pac1. Western blot analysis was used to assess phosphorylation of CaMKI, PKD, and ERK in response to urotensin II (Figures 3A–3F) in Pac1. There was a dose-dependent (Figures 3A–C) and time-dependent (Figures 3D–F) increase in CaMKI phosphorylation (Figures 3A and 3D). PKD phosphorylation (Figures 3B and 3E), and ERK phosphorylation (Figures 3C and 3F) in Pac1 treated with urotensin II. Using 100 nM urotensin II, CaMKI phosphorylation was maximal at 10 minutes, and preceded PKD phosphorylation, which peaked at 15 minutes. Phosphorylation of ERK occurred later and was still increasing at 60 minutes.

### Urotensin II-induced phosphorylation of CaMKI, PKD, and ERK reduced in presence of CaMKK inhibitor in Pac1

To test if CaMKK is an integral target affecting the activation of several downstream effectors in the urotensin II signaling cascade, we used the CaMKK inhibitor prior to the addition of 100 nM urotensin II for 10 minutes, and measured CaMKI phosphorylation via Western blot analysis (Figure 4A). Our results in Figure 4A revealed that STO609 blocked the

Western blot analysis of the time course of CaMKI, PKD, and ERK phosphorylation (A, B, and C) and dose response of urotensin II-stimulated phosphorylation CaMKI, PKD, and ERK (D, E, and F) in Pac1 cells. Densitometry analysis was conducted on Western blots (n = 3, *P ≤ 0.05, **P ≤ 0.01).

**Abbreviations:** Pac1, pulmonary arterial vascular smooth muscle cells; PAVSMC, primary aortic vascular smooth muscle cells; PKD, protein kinase D; CaMKI, Ca²⁺/calmodulin-dependent kinase Type I; ERK, extracellular signal-regulated kinase.
Urotensin II-induced phosphorylation of CaMKI. We also pretreated Pac1 with 250 nM STO609 for 30 minutes, followed by a treatment of 100 nM urotensin II for 15 minutes to measure PKD phosphorylation (Figure 4B). Our findings demonstrated a reduction in urotensin II-stimulated PKD phosphorylation in the presence of STO609 (Figure 4B). We then used 250 nM STO609 for a 30-minute pretreatment, followed by a treatment of 100 nM urotensin II for 30 minutes. Under these treatment conditions, STO609 reduced urotensin II-induced ERK phosphorylation in Pac1 (Figure 4C). By and large, the inhibition of CaMKK reduces urotensin II-induced phosphorylation of CaMKI, PKD, and ERK (Figure 4). Therefore, our results with STO609 establish CaMKK’s involvement in urotensin II receptor signaling (Figure 4).

Characterization of primary cell cultures

Urotensin II-induced signaling mechanisms are poorly understood in vascular smooth muscle cells, therefore we looked at urotensin II receptor signaling in both a cell line and a primary culture. We verified isolation of primary rat aortas by immunostaining the cells with a smooth muscle cell-specific antibody-antimyosin primary antibody for smooth muscle cells. As shown in Figure 5A, more than 70% of PAVSMC are smooth muscle cell-positive. Western blot analysis was used to determine if urotensin II treatment of PAVSMC induces ERK phosphorylation. Our results demonstrate that PAVSMC exposed to 100 nM urotensin II induces phosphorylation of ERK maximally after 15 minutes (Figure 5B). Furthermore, 30 minutes of pretreatment with 250 nM STO609 blocked urotensin II-induced ERK phosphorylation in PAVSMC (Figure 5C). Therefore, our results demonstrate that urotensin II induces the phosphorylation of ERK in PAVSMC, and CaMKK exposure to PAVSMC blocks urotensin II-induced phosphorylation of ERK (Figure 5).

Urotensin II stimulates proliferation of Pac1 and PAVSMC

Studies have linked urotensin II-induced ERK phosphorylation with cellular proliferation in thoracic aortic cells. Therefore, we tested whether urotensin II induces cellular proliferation in Pac1 and PAVSMC. We measured 3H-thymidine uptake as a proliferative assay in Pac1 (Figure 6A) and PAVSMC (Figure 6B). Cellular proliferation was measured by counting numbers of Pac1, and we found that the cell number is greater with urotensin II treatment (Figure 6C). Representative images of urotensin II-treated Pac1 were taken to show differences in cell numbers with urotensin II treatment (Figure 6D). Urotensin II induced proliferation of both cell types in a dose-dependent manner (Figure 6).

CaMKK inhibitor blocks urotensin II-induced cellular proliferation in Pac1 and PAVSMC

Pretreatment with STO609 to inhibit CaMKK blocks urotensin II-induced proliferation of PAVSMC (Figure 7A and B) and Pac1 (Figure 7C). Representative images were taken (Figure 7E), and cellular proliferation was measured by counting cell numbers to show that STO609 blocks urotensin II-induced proliferation in Pac1 (Figure 7D).

Extracellular Ca2+ does not alter urotensin II-induced phosphorylation of CaMKI and cellular proliferation

To determine if 100 nM urotensin II in the presence of extracellular Ca2+ alters CaMKI phosphorylation, the urotensin II-induced phosphorylation status of CaMKI was

measured in 0.1% fetal bovine serum in ACSF media in the presence and absence of Ca²⁺ via Western blot analysis (Figure 8A and 8B). The results indicated no statistical difference between treatment groups (ACSF + urotensin II) and (ACSF + urotensin II + Ca²⁺, n = 3, Figure 8B). To address the role of extracellular Ca²⁺ and 100 nM urotensin II-induced cellular proliferation, we treated cells for 24 hours with reduced serum ACSF in the presence and absence of Ca²⁺ and measured cellular proliferation via ³H-thymidine incorporation assay (Figure 8C). Results in Figure 8C demonstrate that urotensin II treatment in ACSF media, in the presence or absence of Ca²⁺, did not alter the levels of cellular proliferation.

Urotensin II overexpression enhances ERK phosphorylation and proliferation of Pac1

In order to delineate whether urotensin II-induced signaling occurs through the urotensin II receptor, cells were kept in reduced serum for treatment groups (Ad-GoGFP, Ad-urotensin II receptor, Ad-urotensin II receptor + urotensin II, Ad-urotensin II receptor + urotensin II + STO609).
We overexpressed the urotensin II receptor by infecting Pac1 with a urotensin II receptor adenovirus (Ad-urotensin II) in the presence and absence of urotensin II or STO609. Ten percent of serum-treated cells in the presence of the Ad-urotensin II receptor were compared with the reduced serum treatment groups to determine if urotensin II or full serum specifically affects the urotensin II receptor proliferation signaling pathway. We measured downstream targets, such as ERK phosphorylation (Figure 9A), and cellular proliferation (Figures 9B–D). Our results reveal that urotensin II receptor overexpression enhances urotensin II-induced ERK phosphorylation and cellular proliferation of Pac1.

Discussion

The results reported here demonstrate that urotensin II induces Ca\(^{2+}\)/calmodulin-dependent kinase-dependent proliferation of Pac1 and PAVSMC. Furthermore, our present study identified that, in vascular smooth muscle cells, urotensin II-induced phosphorylation of several urotensin II receptor downstream targets can be blocked using a CaMKK inhibitor. These findings suggest that CaMKK inhibition may have therapeutic relevance by blocking cellular proliferation in Pac1 and PAVSMC.

The urotensin II receptor signaling pathway was initially thought to be activated by the single agonist, urotensin II.\(^5\) However, recent evidence identified urotensin II-related peptide as an additional agonist of the urotensin II receptor, similarly activating urotensin II-induced downstream targets.\(^{27}\) Both agonists have been observed to play a role in disease processes, although the scope of our study did not include urotensin II-related peptide effects on urotensin II receptor signaling.\(^{27,28}\) Hirose et al demonstrated that during heart failure, urotensin II-related peptide expression is
Within the past decade, studies have observed the effects of urotensin II binding of the urotensin II receptor in various tissues including the brain, kidney, heart, and vessels. Cellular proliferation in all these tissue types, except for heart, has shown a close correlation with increases in urotensin II levels. Previous studies involving human umbilical vein cells show that urotensin II induces ERK phosphorylation and cellular proliferation. ERK has been recognized as a target for several G-protein coupled receptors, and its activation is correlated with proliferation. ERK activation is dependent on several intracellular signals, including an increase in intracellular Ca++.

Tamura et al. has shown that urotensin II receptor signaling stimulates ERK phosphorylation via the classical pathways involving Ras and Raf in primary thoracic aortic cells. Conversely, Sauzeau et al. revealed via BrdU and cell counting assays that urotensin II stimulates human aortic smooth muscle cell proliferation through RhoA and Rho kinase. Although our studies indicate that activation of cell proliferation by the
urolithin II receptor and its Gq-coupled receptor requires Ca\textsuperscript{2+} activation of CaMK, it is possible that induction of Ras/Raf or Rho kinase pathways may also be involved. Schmidt et al had shown in hippocampal cells that CaMKI stimulates ERK phosphorylation, and conversely reduced ERK phosphorylation using a dominant negative CaMKI or pharmacologic inhibitors to CaMKI, which is consistent with our findings.\textsuperscript{20}

Previous studies examining cellular proliferation identified the sarcoplasmic reticulum as the predominant source of Ca\textsuperscript{2+} release during proliferation. Dramatic changes in Ca\textsuperscript{2+} flux have been linked to cardiovascular disease, such as arteriosclerosis and renal disease.\textsuperscript{34,35} However, the mechanisms inducing intracellular Ca\textsuperscript{2+} flux are not yet well defined. Others have demonstrated that Ca\textsuperscript{2+}/ATPase and sarco/endoplasmic reticulum Ca\textsuperscript{2+}-ATPase pumps could modulate cytoplasmic Ca\textsuperscript{2+} increases during proliferation.\textsuperscript{37} Recent proliferation studies have shown that the intracellular store involved in sarcoplasmic reticulum release (via Ca\textsuperscript{2+}-induced Ca\textsuperscript{2+} release) may occur through the ryanodine receptor.\textsuperscript{36,37} We have not identified the source or the specific mechanism of intracellular Ca\textsuperscript{2+} release, although future studies will entail delineating which intracellular Ca\textsuperscript{2+} store is involved in the urolithin II-induced signaling pathway. Currently it is our belief that the primary mechanism of this Gq signaling-mediated event occurs through inositol triphosphate and modulates the release of Ca\textsuperscript{2+}.

Although our studies indirectly identify Ca\textsuperscript{2+}/calmodulin kinases as the target signaling kinases in the urolithin II-urolithin II receptor pathway, future studies are needed to elucidate urolithin II receptor signaling mechanisms using a urolithin II receptor-specific antagonist. We have used an adenovirus to overexpress the urolithin II receptor, although using siRNA to the urolithin II receptor or a direct inhibitor will determine the involvement of Ca\textsuperscript{2+}/calmodulin kinases in the urolithin II-induced proliferation pathways of vascular smooth muscle cells.

In summary, Pac1 and PAVSMC cultures exposed to urolithin II result in cellular proliferation, and CaMKK inhibitor treatment blocks cellular proliferation. Understanding CaMKK’s role in urolithin II-induced proliferation may provide further insight into potential therapeutic targets for vascular smooth muscle cell proliferation.
Figure 9 Overexpression of the urotensin II receptor in the presence of urotensin II enhances ERK phosphorylation and cellular proliferation in Pac1 cells. A) A representative immunoblot demonstrates that the Ad-urotensin II receptor in the presence of urotensin II, induces ERK phosphorylation in Pac1. B) A representative image of proliferating Pac1 were taken of Ad-urotensin II receptor + serum, Ad-urotensin II receptor, (image 40 × objective) and C) Ad-GFP, Ad-urotensin II receptor + urotensin II, Ad-urotensin II receptor + STO609 (image 20 × objective).
