Dr. Andrea Gokus, andre.a.gokus@fau.de

The blazar Mrk 421 shows frequent, short flares in the TeV energy regime. Due to the fast nature of such episodes, we often fail to obtain sufficient simultaneous information about flux variations in several energy bands. To overcome this lack of multi-wavelength (MWL) coverage, especially for the pre- and post-flare periods, we have set up a monitoring program with the FACT telescope (TeV energies) and the Neil Gehrels Swift Observatory (X-rays). On June 9 2019, Mrk 421 showed a TeV outburst reaching a flux level (> 0.8 TeV) of more than two times the flux of the Crab Nebula at TeV energies. We acquired simultaneous data in the X-rays with additional observations by XMM-Newton and INTEGRAL. For the first time, we can study a TeV blazar in outburst taking advantage of highly sensitive X-ray data from XMM-Newton and INTEGRAL combined. Our dataset is complemented by pointed radio observations by Effelsberg at GHz frequencies. We present our first results of an analysis of the X-ray data obtained with XMM-Newton and Swift, as well as the radio spectra before, during and after the flare.

37th International Cosmic Ray Conference (ICRC 2021)
July 12th – 23rd, 2021
Online – Berlin, Germany

*Presenter
1. Introduction

The active galactic nucleus (AGN) Mrk 421 is the closest blazar with a redshift of $z = 0.031$ [1]. It belongs to the group of high-peaked BL Lacs, meaning the low-energy hump in its typical two-hump-shaped spectral energy distribution (SED) peaks above $10^{15}$ Hz and can show extreme-blazar properties during flares [e.g. 2]. As a BL Lac source, its optical spectrum is strongly dominated by continuum emission, unlike the optical spectrum of flat-spectrum radio quasars, in which emission lines with a width of $> 5\AA$ can be found. While the low-energy hump of a blazar’s SED is caused by synchrotron emission by leptons, the origin of the high-energy hump is still under debate. One scenario is that the highest energies are also produced by leptons via Inverse Compton (IC) processes, while the other scenario includes protons, which can either produce synchrotron radiation or interact with photons, which creates particles that scatter down to high-energetic leptons. Due to its close proximity, Mrk 421 is one of the best studied sources, but we are still far from fully understanding the underlying physics of the observed phenomena across the electromagnetic spectrum. Detailed multiwavelength (MWL) observations during well-defined characteristic emission states hold the potential to yield key observational data but are logistically demanding and challenging to set up.

Mrk 421 has been a known TeV γ-ray emitter since its detection by the Whipple telescope [3], and frequently shows enormous flux variations (see, e.g., [4]), exceeding a flux of 3 times the flux of the Crab Nebula at TeV energies (Crab Units, CU; see, e.g.,[5],[6],[7]), as well as a correlation between optical and GeV emission [8] during flares. In addition, Aleksic et al. (2015) found a correlation between TeV and X-ray emission during non-flaring emission states with zero time lag [9]. Because the correlation persists both in flaring and non-flaring time ranges, these authors conclude that it is difficult to explain the observed long-term variability of Mrk 421 within hadronic scenarios and therefore favour leptonic scenarios.

Mrk 421 belongs to a sample of TeV emitters that show particularly slow apparent jet speeds as measured by Very Long Baseline Interferometry (VLBI) observations in the centimeter radio band. Its viewing angle $\alpha$ has been constrained to $2^\circ < \alpha < 5^\circ$ using VLBA data [10], and the fastest measured jet speeds range from 0.09 c [11] to 0.4 c [12]. The physical conundrum here is that the most energetic blazars seem to show relatively low jet bulk motion indicative of only mildly relativistic plasma, which contradicts the extreme γ-ray properties. This problem had been coined the Doppler crisis. As a solution, Hervet et al. (2019) propose that the observed knots are actually recollimation shocks in which particals get accelerated along the jet [13]. As a test target they chose Mrk 421, and studied its 13 years long X-ray light curve, obtained with Swift. They probed for an intrinsic variability pattern caused by particles moving through each radio knots, which they found, but a similar study of the TeV light curve for Mrk 421 is necessary to establish their theory.

In this work, we present TeV, X-ray, and radio data from Mrk 421, which were taken during a flare of the source in June 2019. The flare had been detected by the Cherenkov telescope FACT, and MWL follow-up observations had been performed with the Neil Gehrels Swift Observatory (Swift), XMM-Newton, INTEGRAL, and the 100m-dish radio telescope at Effelsberg. The success of the rapid follow-up observations is owed to our MWL program, which has been planned in great detail and run since 2012 [14]. The setup of this MWL program will be presented in this work as well.
2. Monitoring program

In order to fully comprehend the emission of blazars, and given their very variable nature, it would be desirable to obtain long-term uninterrupted data sets, that cover the full electromagnetic spectrum. As this is logistically not feasible, we have set up a program to combine a long-term snapshot monitoring of selected blazars with deep Target-of-Opportunity (ToO) short-term quasi-simultaneous MWL observations during characteristic flaring states. In this program, we make use of the Cherenkov telescope FACT and the X-ray satellite Swift to monitor the flux of Mrk 421 at TeV (with nightly cadence), and X-ray and optical/UV energies (with 4-5 day cadence), respectively. In addition, we defined ToO criteria to trigger further instruments for full MWL coverage, including INTEGRAL, XMM-Newton, and the 100-m radio telescope in Effelsberg. The program has been run since 2012 and first results from a first moderately bright flare of Mrk 421 have been presented by Kreikenbohm (2019) [14].

On 2019 June 9, FACT registered a TeV flux brighter than 2 CU, and we sent out a trigger to Swift, XMM-Newton, and INTEGRAL at 2019 June 9 22:30 UTC. Daily Swift pointings were requested to obtain a dense monitoring at X-ray energies during and after the flare, while a deep pointing with XMM-Newton was performed to allow a detailed variability study on time scales smaller than one day. Because Swift and XMM-Newton cover the X-ray energy range from roughly 0.5 – 10 keV, the integral mission is included in our program to gain data for the harder X-ray range from 15 keV up to 10 MeV, as well. Figure 1 shows the timeline of our MWL observations from 2019 June 8, 12:00 UTC until 2019 June 14, 12:00 UTC, with a true representation of the observation times in relation to each other.

3. Instruments and Data
3.1 The First G-APD Cherenkov Telescope

The First G-APD Cherenkov Telescope (FACT) observes the γ-ray sky at energies above 300 GeV since October 2011 [15]. Its major objective is to monitor a small sample of known TeV-emitting blazars continuously in order to obtain an unbiased, long-term view on the gamma-ray activity of these sources. During this campaign in 2019, FACT has observed Mrk 421 for about 570 hours of which 10.7 hours are presented here. Based on the monitoring of FACT, the trigger
to the X-ray satellites XMM-Newton and INTEGRAL was sent. The data were analyzed using the Modular Analysis and Reconstruction Software (MARS) [16]. In the context of the database-based analysis [17], the ‘light curve cuts’ as described in [18] were used for background suppression. The data quality selection was done based on the artificial trigger rate [18, 19]. More details on the analysis are available in [20].

3.2 The Neil Gehrels Swift Observatory

The Neil Gehrels Swift Observatory has three instruments on-board: the UV/Optical Telescope (UVOT), the X-ray Telescope (XRT), and the Burst Alert Telescope (BAT) [21]. In this work, we will only present the data from Swift/XRT, which observes X-rays in an energy range between 0.5 keV and 10 keV, and focus on the analysis of observations between MJD 58636 and MJD 58652. Each of these observations was taken in the window timing mode, and with a net exposure time of 1 ks. We extract the spectra using the xrtpipeline available within HEASoft (v6.26). We fit all spectra with an absorbed powerlaw, for which the influence of photoelectric absorption was frozen to a value derived from the measured column of neutral hydrogen \( N_H = 0.0133 \) [22]. The X-ray flux of Mrk 421 around the time of the flare are plotted in Fig. 2.

3.3 The X-ray satellite XMM-Newton

The XMM-Newton satellite carries three Wolter X-ray telescopes as well as an optical telescope. X-ray spectra are taken with three cameras and different CCD chips [23]. The observation on Mrk 421 on 2019 June 10 (ObsID: 0845000901) was taken in timing mode, however, because of the immense flux increase during the observation, it was necessary to change the observational mode to burst mode. The data of the EPIC-pn camera was reduced using standard methods\(^1\) of the XMM-Newton Science Analysis System (Version 18.0.0). Because of pile-up in timing mode, we excluded the inner five columns (RAWX = 36-40) of the chip. We extract a light curve with a time binning of 100 s, which is shown in Fig. 3 (left). The count rates measured for Mrk 421 are the highest rates ever seen for this source by XMM-Newton. In addition, we extract time-resolved spectra with an exposure of 3 ks each, and fit these spectra with the same model and \( N_H \) value as the Swift spectra. The resulting flux values are shown in the XMM-Newton light curve in Fig. 2.

3.4 The Effelsberg 100m radio telescope

We used the 100m-dish radio telescope in Effelsberg to observe Mrk 421 at a broad range of frequencies\(^2\) across the cm band before (May 5), during (June 7, 11, 12), and after (July 5, November 4, 16) the TeV flare. The observations have been performed as cross scans in azimuth and elevation over the (unresolved) source. Pointing offsets were corrected and individual subsists were averaged. After corrections for the atmosphere’s opacity and the gain-elevation effect, the flux densities were calibrated using suitable calibrators like 3C286 [see, e.g., 24].

4. Variability analysis

Here, we present the \( \gamma \)-ray light curve for energies above 700 GeV, obtained with FACT, and the X-ray light curve, composed of Swift and XMM-Newton pointings. A thorough variability analysis,

---
\(^1\)https://www.cosmos.esa.int/web/xmm-newton/sas-thread-pn-spectrum-timing
\(^2\)Secondary receiver: 4.85, 10.45, 14.25, 16.75, 19.25, 21.15, 22.85, 24.75, 35.75, and 38.25 GHz
also including other wavelengths, will be presented in a later work.

The γ-ray and X-ray light curves are shown in Fig. 2. We additionally mark the time, when we sent a trigger to other telescopes for MWL follow-up observations. After the trigger, the source remained in a high TeV state. Two and three nights later, respectively, the γ-ray flux even exceeded the flux at the time of the trigger. Due to the dense Swift monitoring and the long XMM-Newton observation, we were able to track the behaviour in the X-ray energy regime in unprecedented detail. In the X-rays, the highest flux for the depicted time range is measured at \( \sim \) MJD 58645.5. After that, the flux seems to decreases over about three days until the flux is at the same level as before the flare.

We compute the power spectral density (PSD) from the 100s binned XMM-Newton light curve, yielding a Nyquist frequency \( f_{\text{Ny}} = 5 \cdot 10^{-3} \text{ Hz} \). We use the Leahy normalisation in order to directly distinguish Poisson noise from source intrinsic variability. The resulting PSD is shown in Fig. 3. At a frequency of \( 10^{-3} \text{ Hz} \) (\( \sim 16 \text{ minutes} \)), the power reaches the level of the Poisson noise.

**Figure 2:** X-ray and γ-ray light curves of Mrk 421 between 2019 June 2 (MJD 58636) and 2019 June 20 (MJD 58654). The γ-ray flux unit is given in ph cm\(^{-2}\) s\(^{-1}\), and the X-ray flux units are given in erg cm\(^{-2}\) s\(^{-1}\). The trigger time for follow-up observation is marked by the grey vertical line.

**Figure 3:** *Left:* XMM-Newton light curve with a bin size of 100s. Data taken in timing and burst mode are shown in blue and red, respectively. *Right:* Power spectral density computed from the XMM-Newton light curve with 100s binning. The horizontal line marks the level of Poisson noise.
5. Radio spectra with the Effelsberg 100m radio telescope

In Fig. 4, we show radio spectra taken with the 100m-dish radio telescope Effelsberg between 4.85 GHz and 38.25 GHz before, during, and after the TeV flare. In between these times, no prominent spectral changes can be observed, except for a slight flattening on July 5, which is ≈ 1 month after the TeV and X-ray flare. The spectrum for June 11/12 exhibits the highest overall flux, but these variations are well within the typical range that can be observed for Mrk 421 (see, e.g., [25] in these proceedings for a radio light curve of Mrk 421 in the 14mm and 7mm bands, taken as part of the TELAMON program). This shows that the γ-ray flare has not caused a major response of the parsec-scale radio jet as probed on a cadence of 5 months after the event.

6. Summary and Outlook

We have set up a sophisticated MWL program to fully characterize a blazar flare including pre-flare information, quasi-simultaneous MWL data during the flare and long-term follow-up observations. The combination of dense X-ray and VHE γ-ray monitoring with pre-approved trigger opportunities at facilities across the electromagnetic spectrum, has yielded a unique MWL data set of a flare in the closest blazar Mrk 421 in June 2019, detected by FACT. The high activity at γ-rays lasted ≈ 4 days, with the highest flux being measured on June 11, which seems to coincide with the highest X-ray flux. During the XMM-Newton observation, we find sub-hour variability in the X-rays. The pc-scale radio jet has not shown any major response to the high-energy activity. In a later work, we will perform a more thorough analysis of the MWL data, including a deeper analysis of the behaviour at X-ray energies and in the TeV band.

Acknowledgments
