OBJECTIVE The authors aimed to compare the efficacy of lumbar vertebral body Hounsfield units (HUs) and pedicle HUs at predicting pedicle screw loosening.

METHODS The authors retrospectively assessed 143 patients with L3–5 instrumentation. The patients were classified into one of two groups based on the status of their L3 screws (a screw loosening group or a control group). The pedicle HUs and vertebral HUs of L3 were measured using preoperative lumbar CT scans, and the pedicle HUs were measured in two ways: by excluding or by including cortical bone.

RESULTS The screw loosening rate was 20.3% (n = 29/143) at the 12-month follow-up. The vertebral body HUs and pedicle HUs in the screw loosening group were lower than those in the control group (vertebral body group: 98.6 HUs vs 121.4 HUs, p < 0.001; pedicle excluding cortical bone: 208.9 HUs vs 290.5 HUs, p = 0.002; pedicle including cortical bone: 249.4 HUs vs 337.5 HUs, p < 0.001). The pedicle HUs tended to have a higher area under the receiver operating characteristic curve value in predicting screw loosening, compared with that of vertebral body HUs, but the difference was not statistically significant (p > 0.05). Among patients with low vertebral body HUs of ≤ 130, the loosening rate was much lower in patients with pedicle HUs of ≤ 340 than in those with pedicle HUs of > 340 (31.0% vs 13.0%, respectively; p < 0.05).

CONCLUSIONS Vertebral body HUs alone are insufficient to accurately evaluate the risk of pedicle screw loosening. Therefore, it is important to collect both the pedicle HU and vertebral body HU measurements for surgical planning.

KEYWORDS CT Hounsfield units; pedicle bone density; screw loosening; vertebral bone density

Pedicle screw loosening is one of the most common complications of lumbar posterior fixation.1–3 Some studies have found that the screw loosening rate was 1%–27%.4,5 in normal patients and as high as 60% in osteoporotic patients.5,7 Röllinghoff et al.9 found that 20% of patients with screw loosening developed back pain, and screw loosening was one of the major reasons for revision surgery.9,10 In addition, many cases showed that screw loosening can result in other complications such as screw breakage, nonunion, pseudarthrosis, and kyphosis.11,12 Therefore, it is important to prevent loosening of the screws.

It is well known that osteoporosis is a risk factor for pedicle screw loosening.13–15 Therefore, preoperative bone mineral density (BMD) evaluation is critical for surgical planning. Previous studies found that the BMD of the vertebral body and the pedicle were closely related to the stability of fixation.16–19 Compared with vertebral bone density, studies have shown that bone density of the pedicle has a greater impact on the stability of the pedicle screw,19 and the bone density of the intrapedicular segment is more important for the stability of the screw than the bone density of the screw tip segment and the segment close to the vertebral body.17,18 About 60% of pullout strength is de-
termined by the pedicle instead of the vertebral body. These may be due to the differences in the structure and the regional BMD between the pedicle and the vertebral body. Dual-energy x-ray absorptiometry (DXA) is the most common method for evaluating BMD and diagnosing osteoporosis. However, DXA might overestimate the BMD of the lumbar spine and miss osteoporosis in patients with lumbar degenerative disease, especially for degenerative lumbar scoliosis.

Apart from DXA, the vertebral body Hounsfield unit (HU) value measured on clinical CT scans can also help detect osteoporosis. Several studies have shown that the HU value of the vertebral body is closely related to screw loosening. However, very few studies have investigated whether the HU value of the lumbar pedicle is related to screw loosening.

This study was designed to compare the efficacy of using the HU values of two different regions—the vertebral body and the pedicle—in predicting screw loosening. Considering that screw loosening is the result of multiple factors, we only assessed patients with L3–5 instrumentation in this study and focused on the screw loosening found at L3 in order to reduce the influence of potential factors other than CT HUs.

### Methods

#### Patients

This study was approved by the institutional review board of our hospital. The need to obtain informed consent was waived due to the retrospective nature of the study. A total of 143 patients who underwent primary transpedicular lumbar fixation for lumbar degenerative diseases from July 2011 to December 2017 were analyzed retrospectively. The inclusion criteria were as follows: 1) instrumentation from L3 to L5 in patients aged > 50 years at the time of surgery; 2) follow-up data for at least 12 months; and 3) lumbar CT scans obtained within 3 months before the surgery. To exclude other confounders as much as possible, we established the following exclusion criteria: 1) history of congenital spinal deformity, spinal trauma, spinal tumor, spinal tuberculosis, ankylosing spondylitis, or previous spinal surgery; 2) presence of metabolic bone disease or long-term use of medicines like corticosteroids, which can influence BMD; and 3) patients who underwent revision surgery due to non-screw loosening causes, such as intraoperative nerve injury, postoperative wound hematoma, and adjacent disc degeneration in the 12 months after primary surgery. Screw loosening was defined as a clear zone of minimal thickness of ≥ 1 mm around the pedicle screw on radiography.

A senior spine surgeon (Z.S.) independently evaluated the radiographs. All patients’ surgeries were planned and performed by the same surgical team. At the 12-month follow-up visit, patients exhibiting screw loosening at L3 were assigned to the screw loosening group. The remaining patients were assigned to the control group.

### Estimation of Bone Density

All patients underwent preoperative lumbar CT (Definition, Siemens). The tube voltage of the CT scans was set at 120 kV. The average of the region of interest (ROI) HU value was calculated using a PACS. An axial plane at the mid-vertebral body was chosen for the measurement of vertebral body HU (Fig. 1). The ROI was selected as a clear zone of minimal thickness of ≥ 1 mm around the pedicle screw on radiography. A senior spine surgeon (Z.S.) independently evaluated the radiographs. All patients’ surgeries were planned and performed by the same surgical team. At the 12-month follow-up visit, patients exhibiting screw loosening at L3 were assigned to the screw loosening group. The remaining patients were assigned to the control group.

### Statistical Analysis

Statistical analysis was performed using SPSS version 23 (IBM Corp.) and MedCalc Statistical Software version.
15.6.1 (MedCalc Software). The independent-samples Student t-test was used for continuous variables. Chi-square testing was used for categorical data. Using MedCalc Statistical Software, the vertebral body HU, the HU values of the pedicle excluding cortical bone and the pedicle including cortical bone, and the diameter of pedicle were analyzed in association with screw loosening using receiver operating characteristic (ROC) curves. Logistic regression analysis was performed to determine which parameter was independently associated with screw loosening.

Results

Demographics

The screw loosening rate was 20.3% (29/143) at L3 in the patients with L3–5 instrumentation. Compared with the control group, patients’ BMI values in the screw loosening group were significantly higher (p = 0.049), but no significant differences in sex or age between the two groups was found (Table 1).

HU Values of Vertebral Body and Pedicle

A comparison of HU values of the vertebral body and pedicle between the two groups is listed in Table 1. The Pearson correlation coefficient between CT HU values of the vertebral body and the pedicle excluding and including the cortex was 0.409 (p < 0.001) and 0.456 (p < 0.001), respectively. The CT HU values of the L3 vertebral body and pedicle (excluding and including cortical bone) in the screw loosening group were lower than those in the control group (vertebral HU value: p < 0.001; pedicle HU value excluding the cortical bone: p = 0.002; and pedicle HU value including the cortical bone: p < 0.001). The mean pedicle diameters in the screw loosening group were higher than those in the control group (p = 0.008). According to the paired t-test, the pedicle HU value including the cortical bone was significantly higher than that of the pedicle HU value excluding the cortical bone (319.6 ± 121.7 vs 274.0 ± 126.1, p < 0.001).

ROC Curve Analysis

We established the ROC curve to evaluate the validity of using CT HUs to predict screw loosening. They are shown in Table 2. The pedicle CT HUs (excluding and including cortical bone) had larger areas under the curve (AUCs) than those of the vertebral CT HUs, but there was no significant difference (p > 0.05).

BMD Analysis of Screw Loosening

According to the ROC analysis, we identified the HU cutoff (take a multiple of 10) for identifying high-risk patients for screw loosening. The cutoff value of high sensitivity (about 90%) was set at 130 HUs for the vertebral body and 340 HUs for the pedicle (including cortical bone). The cutoff value for high specificity (about 90%) was set at 70 HUs for the vertebral body and 180 HUs for the pedicle. We divided the patients into 4 groups accord-
of pedicle screws at L3.

Table 3. Thresholds of CT HU values of the pedicles and vertebral bodies

| Screw Loosening Rate* | CT HU of VBs ≤130 | CT HU of VBs >130 |
|-----------------------|-------------------|-------------------|
| CT HUs of the pedicle ≤340 | 31.0% (22/71)     | 17.6% (3/17)     |
| CT HUs of the pedicle >340 | 13.0% (3/23)    | 3.1% (1/32)      |

VB = vertebral body.

* Number of screw loosening/total number.

Logistic Regression of Risk Factors and Screw Loosening

We entered the risk factors with a $p$ value < 0.1 into logistic regression, including BMI, mean diameter of the pedicle, and CT HU. Since vertebral body HUs had significant linear correlation with pedicle HUs, they were not put into the regression model at the same time. As for the regression analysis including BMI, pedicle diameter, and a vertebral body HU of ≤ 130, the following results were found: BMI, OR 1.192, 95% CI 1.020–1.393, $p = 0.027$; pedicle diameter, OR 1.349, 95% CI 1.062–1.713, $p = 0.014$; and vertebral body HU of ≤ 130, OR 6.555, 95% CI 1.770–24.272, $p = 0.005$. As for the regression analysis including BMI, pedicle diameter, and pedicle HU of ≤ 340, the following results were found: BMI, OR 1.171, 95% CI 1.013–1.353, $p = 0.032$; pedicle diameter, OR 1.287, 95% CI 1.014–1.633, $p = 0.038$; and pedicle HU of ≤ 340, OR 4.848, 95% CI 1.520–15.465, $p = 0.008$.

Discussion

This study found that both the CT HU values of the pedicle and the vertebral body were closely related to screw loosening. The lower the CT HU values, the higher the possibility of screw loosening. Furthermore, patients with a low vertebral body HU value are not always at a high risk of screw loosening, especially when they have a high lumbar pedicle HU value.

It is well known that pedicle screw loosening can arise from many factors other than BMD, such as the vertebral level of screws, length of fixation, and so on. To decrease the influence of confounding factors, this study only chose patients with L3–5 instrumentation, focusing on the status of pedicle screws at L3.

In this study, the screw loosening rate was up to 20.3% (n = 29/143), which is comparable with the results of previous studies. We found that patients with a high BMI were at a higher risk of screw loosening. Furthermore, we found that the mean diameter of pedicles in the control group was smaller than that of pedicles in the screw loosening group. According to the logistic regression, the pedicle diameter was also an independent predictor of screw loosening. It may be related to the fact that the screw gets more pullout strength when it is close to the cortical bone. However, in osteoporotic patients, some studies have found that a larger-diameter screw does not increase its stability.

Recently, the CT HU value has been widely used for the evaluation of BMD and screening for osteoporosis. A few studies have proven that the CT HU value of the vertebral body is closely related to screw loosening. It is well known that most of the pullout strength is determined by the lumbar pedicle instead of the vertebral body. However, there are a few studies investigating the effect of the pedicle CT HU on screw loosening.

In this study, we found that the CT HU values of both the pedicle and the vertebral body were significantly lower in the screw loosening group than that in the control group. Owing to different trabecular architecture and a higher biomechanical relevance, it was reported that the intrapedicular segment is more important for the stability of screw than the segment of the screw tip and the segment closing to the vertebral body. In agreement with previous studies, we found that the pedicle HU tended to have a higher AUC in predicting screw loosening than the vertebral body HU. However, there was no statistically significant difference. The possible reason is that the vertebral body HU is positively correlated to the pedicle HU (excluding cortex: R = 0.409, $p < 0.001$; including cortex: R = 0.456, $p < 0.001$). The screw loosening rate of patients with the vertebral body HU of ≤ 130 and pedicle HU (including cortical bone) of ≤ 340 HU is much higher than patients with the vertebral CT HU of ≤ 130 and pedicle HU (including cortical bone) of > 340 (31.0% vs 13.0%, $p < 0.05$). This proves that low vertebral body HU is not always associated with high risk of screw loosening, especially for patients with low pedicle HU. Hence, it is important to consider the BMD of both the pedicle and the vertebral body when making the preoperative evaluation.

A previous study has collected the BMD of the screw’s pathway to predict screw loosening by 3D image analysis software. However, on axial images of the vertebral body, the screw pathway’s CT HU value cannot be measured directly with routine PACS. If we focus on the CT HU value of the screw’s pathway, the measurement may be complicated and cannot be applied in routine clinical practice. Thus, we opted to use the routine method of measuring the preoperative lumbar CT HU values of the vertebral body and the pedicle to predict screw loosening, which is convenient and simple.

There are two main limitations to this study. As this was a retrospective study, further prospective studies are warranted to validate our findings. Next, this study only focused on the HU of L3. However, the CT HU values of the vertebral body and the pedicle may be different at different vertebral levels, leading to different threshold values for predicting screw loosening. Further research is recommended in this regard.

Conclusions

Both pedicle and vertebral body CT HU values are associated with screw loosening, which can be regarded as indicators of screw stability. Moreover, the lower the CT HU values are, the higher the risk of screw loosening. The pedicle CT HU tended to have a better ability in predicting screw loosening than the vertebral body CT HU. In addition to vertebral body BMD, assessment of the pedicle
BMD using CT may potentially improve preoperative surgical planning.
