Abstract: Phosphorus is a biogenic element with a high importance within the food chain. Regrettably, there are limited amounts of phosphorus within minerals naturally occurring in the environment. Its scarcity leads to a necessity of closed loop economy, where this element could be obtained by the processing of various waste materials. Modern agriculture needs to provide sufficient amounts of phosphorus to plant organisms encountering problems with the bioavailability of nutrition. In this research, a post-processed animal waste material (calcined bone) was utilized to reclaim phosphorus and reintroduce it into the environment in a form of foliar fertilizer. The calcined bones were subjected to chemical transformation with nitric acid solution. The solubilization of bones was followed by laboratory-scale pot experiments, in which the fertilizer was used for the cultivation of maize plants. In the field experiments, the fertilizer was additionally fortified with boron and molybdenum elements. It was observed that the utilization of the fertilizer had a positive impact on maize plants, i.e., improvement in the biomass production of aboveground and underground parts of the plants. The amount of chlorophyll increased in comparison to control plants. Maize grain production was increased by approximately 600 kg ha⁻¹).

Keywords: closed loop economy; calcined bones; phosphorus; foliar fertilizer; maize

1. Introduction
Phosphorus is a biogenic element that is crucial for sustaining life in various forms, whether microorganisms, plants or animals [1–3]. Therefore, compounds with phosphorus in their structure have great importance within the food chain. Historically, guano was used as the source of phosphorus for the growth and development of plant organisms in areas of cultivation. In the last century, minerals containing phosphorus became a dominant source of this element. Modern agriculture is based on artificial fertilizers that include elements such as N, P, K and other microelements and macroelements [1]. The need to provide sufficient amounts of phosphorus to plant organisms encounters two major obstacles. On the one hand, there is a scarcity of this element within natural minerals, and, on the other hand, minerals that contain phosphorus in various forms may be contaminated with a number of heavy metals. Moreover, the occurrence of phosphorus in various minerals does not always result in
its bioavailability to various plants. It is reported that 67 billion t of phosphate minerals are present in the world, with the concentration of phosphorus (expressed as $P_2O_5$) within the range of 28% to 39% [2]. Unfortunately, it is expected that, in the next century, over a half of these deposits will be used up. Another challenge is the uneven distribution of this element within the world, thus some countries are left without any sort of natural supply of this resource. Most reserves of this resource lay in the earth crust of African countries, such as Morocco, Algeria, South Africa, some in the Middle East (Syria) and others in China. Together, those countries control almost 90% of the total supply of this resource [3]. Another obstacle for providing plants with the sufficient amount of phosphorus is the necessity of the processing of raw minerals in order to prepare a fertilizer that would include phosphorus elements in a bioavailable form. Due to the scarcity of this resource and a high degree of losses during agricultural runoff, erosion and animal waste, there is a high emphasis put on the recovery of this element from various processing chains [4]. The solution of this problem might be a closed loop economy with maximal recovery of this valuable element [2,5]. The recovery of phosphorus from different waste, such as manure, wastewater, sewage sludge, digestate from biogas production or ashes from sewage sludge incineration, and reintroduction as a fertilizer is considered a good approach [6,7]. Ehmann et al., 2017, developed a method to reclaim phosphorus and other nutrients from manure. The generated biocarbons that were rich with phosphorus-containing compounds were tested in pot experiments aimed at the comparison of their efficiency with conventional phosphorus fertilizers. It was concluded that the biocarbons can improve the impact of the phosphorus fertilizers [7].

An attractive alternative source of phosphorus may be the sewage sludge after a treatment. Sewage sludge that was subjected to fermentation in various conditions was tested in field conditions utilizing various doses as a fertilizer. The efficiency of the fertilization process was investigated using a number of analytical techniques including 31P-NMR. It was concluded that fertilization with sewage sludge can be beneficial in the initial vegetation period. Furthermore, it was indicated there was a great diversity between the efficiency of the utilized sewage sludge types [8].

One of the possible sources of phosphorus is the utilization of animal waste and, in particular, animal bones. Bones consist of 70% of inorganic minerals (apatites) and organic compounds [1,9]. Already in 1770, when it was discovered that phosphorus is one of the minerals present in bones, a number of attempts were made to recover it. For many years, bones were substrates from which phosphorus and phosphoric acid were produced. In comparison to minerals that may be obtained via mining, animal bones contain a significantly lower amount of contaminants such as heavy metal ions [10].

Before the numerous cases of Bovine spongiform encephalopathy (BSE) disease, caused by the consumption of contaminated bone meal, the meat and bone meal (MBM) could be utilized for the recovery of some amounts of phosphorus [11]. Nowadays, other methods for the recovery of this element are needed. One such method is the utilization of microbes to solubilize phosphorus-rich minerals [5,6,10]. Demirbas et al. developed a method for the recovery of phosphorus from calcined bones using hydrochloric acid solutions with various concentrations. The optimization of the solubilization process was carried out using the Taguchi fractional design method. The efficiency of the recovery process was established at 67.2% $P_2O_5$. Although the process efficiency is satisfactory, the obtained fraction is not suitable for direct fertilization due to the high content of Cl ions, which cause soil salinity [12].

Phosphate deposits may originate from teeth, bones and excrements of marine organisms or pre-historic life. Those deposits may be reclaimed into the phosphate cycle within the food chain. Microorganisms can be responsible for the breakdown of phosphates using enzymes such as phosphatase, phytase, and nucleotidase [10]. The solubilization of phosphates may also occur through the generation of inorganic and organic acids, which eventually leads to the dissolution of solid phosphates [13–15]. This indicates that the utilization of acids to solubilize phosphorus present in minerals, which are a part of bones, is a viable option to reclaim this element. However, using acids
such as sulfuric acid leads to the formation of the so-called phosphogypsum, which results in the loss of bioavailable phosphorus.

The aim of this work was to develop an effective method for the solubilization of mineral compounds from calcined bones and to use it to prepare foliar fertilizer. The fertilizer was tested in both pot experiments and field conditions.

2. Materials and Methods

2.1. Materials

The bone material originated from a cattle slaughterhouse and was thermally processed at temperatures in the range of 850–950 °C and grounded to achieve particles no larger than 2 mm.

2.2. The Process for the Solubilization of Minerals from Calcined Bones

The raw bone material obtained after calcination and grounding was weighed and placed into conical flasks and then nitric acid solution was added. The reaction mixtures were prepared by mixing components such as 42 g of 65% nitric acid (V) that was bought from Chempur (Piekary Śląskie, Poland) with 120 g of deionized water and 25 g of calcined bones. Next, the slurries were stirred by a magnetic stirrer at 500 rpm. Solubilization was carried out for 1 h at 20 °C. After that, the contents of the flasks were transferred to falcons and centrifuged for 5 min at 2500 rpm. The supernatant obtained was decanted and the precipitate was rinsed with distilled water and centrifuged again under identical conditions. The combined supernatant was transferred into round-bottom flasks, and then most of the solvent was removed using a Heidolph Hei Vap Adventage (Schwabach, Germany) rotary evaporator under reduced pressure (0.01 MPa). The residue, in a form of a paste, was transferred into a pre-tared petri dish and dried to a constant weight. Next, the fractions obtained after crushing in a porcelain mortar were kept for further analysis as well as, after dilution, use as a foliar fertilizer (Table 1.).

Table 1. Determined mineral composition of the bone waste material.

|   | Na   | K   | Mg  | Ca  | P   | N   | Fe  | Mn  | Zn  | Cu  |
|---|------|-----|-----|-----|-----|-----|-----|-----|-----|-----|
| g kg⁻¹ | mg kg⁻¹ |  |  |  |  |  |  |  |  |  |
| 4.74 ± 0.43 | 37.48 ± | 16.77 ± 1.25 | 492.46 ± 9.51 | 161.13 ± 0.7 | 0.06 ±0.01 | 21.03 ± 0.80 | 80.76 ± 2.22 | 10.40 ± 0.04 | 40.44 ± 0.97 |

Note. The results are presented as the mean value ± SD (standard deviation) (n = 3).

The process conditions were scaled up to an industrial scale by increasing the apparatus dimensions. For the solubilization procedure, a reactor equipped with a propeller stirrer with a volume of 1 m³ was utilized. A total of 480 kg of water was placed into the reactor and, next, 100 kg of grounded bones was introduced. Then, 168 kg of 65% nitric acid was introduced into the reactor. The acid was dosed into the reactor for one hour. The obtained solution was then filtrated with a filter cloth with a pore size of 25 μm. The recovery of the mineral compounds present in the solution was at the level of 95%. In the next step, the solution was introduced into a fluidized bed granulator (Glatt GmbH, Binzen, Germany) that was filled with boric acid, which had a particle size of 0.2–0.5 mm, and ammonium heptamolybdate. The granulation procedure was conducted by the spraying of the solution on the surface of boric acid coupled with a drying process at a temperature of 45 °C.

2.3. Description of the Pot Experiments

The one-way pot experiment was carried out in the vegetation hall. The external conditions, such as temperature and humidity, were controlled. For lighting during cultivation, an LED based technology was used on the plants. The variable factor investigated was the effect of the developed foliar fertilizer on both the growth and the development of the maize variety Farm Gigant (thousand kernel weight = 264 g). In the pot experiments, there were control plants (without foliar fertilizing)
and three groups of plants, which were fertilized with different doses of the product solution—11.8 mg pot$^{-1}$ (1.0 kg ha$^{-1}$), 23.6 mg pot$^{-1}$ (2.0 kg ha$^{-1}$) and 35.4 mg pot$^{-1}$ (3.0 kg ha$^{-1}$). The experiment was carried out in 10 replications for each variant in a completely random arrangement (Table 2).

The experiments were carried out in the production pots, wherein 3 kg of soil with a granulometric composition loamy sand of mildly acidic pH (pH: KCl, 6.35; H$_2$O, 6.52) was placed. During the experiment, a constant humidity of 50% of the maximum water-holding capacity (WHC) was maintained for the soil in the vases. The application of the test solutions of fertilizer doses was conducted manually by diluting the developed fertilizer in water; the fertilizer volume used was 200 dm$^3$ ha$^{-1}$.

The application of the foliar fertilizer was conducted at an ambient temperature of 22 $^\circ$C during the 5th leaves phase (BBCH 15) [16]. Then, 14 days after the second application of the fertilizer, a measurement of the relative amount of chlorophyll within the flag leaf was conducted using a device, SPAD 502 (Konica-Minolta INC, Osaka, Japan) [17]. Next, the plants from each vase were isolated and cleaned up from the soil particles. The maize plantlets were divided into aboveground and underground parts, and both were subjected to further analyses.

2.4. Description of the Field Experiments

For field experiments, a foliar fertilizer was used; the base of the product was an isolate (Table 3) with compounds of boron (395 g kg$^{-1}$ Boric acid, Parnter Chem, Lublin, Poland) and molybdenum (3.5 g kg$^{-1}$ Ammonium heptamolybdate (NH$_4$)$_6$Mo$_7$O$_{24}$), Centrum Metal Odczynniki Chemiczne Midas-Investment, Falenty, Poland) (Table 4). The presence of boron is responsible for correct pollination and filling of the cobs with grain. Also, the presence of B in maize strengthens the stiffness of the stems, which reduces lodging and protects plants from pests. Insufficient molybdenum content within plants causes the inhibition of chlorophyll synthesis, an increase in the content of inorganic P, which should be incorporated into organic structures under normal conditions, and a decrease in pollen production and lifetime. For the spraying procedure, Matrot maestria, Tecnoma laser, Allaey and Rau Vicon kverneland sprayers were utilized. The sowing density was 70,000 seeds ha$^{-1}$, and the weeds were controlled using standard pest control procedures for maize cultivation; the maize variety Farm Gigant was used. The verification of the tested foliar fertilizer was carried out in field conditions, in field experiments in 2018, in 8 locations in Poland. The area of each location was 5 ha. The experiment was carried out in parallel in different regions (I, II and IV), more or less favorably for the cultivation of maize (Figure 1, Table 2).

Table 4. Mineral composition of the isolate with boron and molybdenum compounds.

| Mineral Composition of Foliar Fertilizer | P (g kg⁻¹) | N (g kg⁻¹) | Na (g kg⁻¹) | K (g kg⁻¹) | Mg (g kg⁻¹) | Ca (g kg⁻¹) | B (g kg⁻¹) | Mo (mg kg⁻¹) | Fe (mg kg⁻¹) | Zn (mg kg⁻¹) | Ca (mg kg⁻¹) |
|-----------------------------------------|------------|------------|-------------|------------|-------------|-------------|------------|--------------|--------------|--------------|--------------|
|                                         | 48.8       | 12.5       | 4.2         | 1.2        | 4.4         | 80.3        | 70         | 2            | 10           | 8            | 1.5          |

The most favorable climatic conditions for growing maize occur in region I, which covers the southwestern and southeastern parts of Poland. This region is characterized by the longest vegetative period, favorable rainfall distribution and high average air temperature. In region II, covering the central part of Poland, in warm summer and favorable distribution of rainfall, a high yield of maize grain is also obtained. Unfavorable conditions that occur in the foothill regions (region IV) limit the cultivation of maize in these areas. The field experiment scheme was designed to replace the 3 year period scheme, since the tested fertilizer was tested in parallel in several locations, characterized not only by different climatic but also soil conditions (Table 2).

The applied fertilizer was tested in May. The average sum of rainfall ranged from 200 mm in location A to 405 mm in location G, and the average air temperature during the experiment ranged from 17.2 °C (location C) to 18.4 °C (location B). The granulometric composition of soils on which the experiments were carried out corresponded to sand (location A), sandy loam (B, D, E) and loamy sand (C, F, G, H) (Table 1). The pH values of these soils were moderately acidic (5.80) to slightly alkaline (7.42). Soil samples of soils on which experiments were carried out were also characterized by diversified abundance in digestible forms of macroelements. The content of available magnesium ranged from 55 (location C) to 266 mg kg⁻¹ (location H), digestible potassium from 79 (location B) to 323 mg kg⁻¹ (location F), and phosphorus from 10.9 (location B) to 92 mg kg⁻¹ (location C).

In the field experiment, a dose of 3.0 kg ha⁻¹ of the fertilizer preselected in the pot experiment was tested in parallel to the control plant (no fertilization). The working fluid in the amount of 200 dm³ ha⁻¹ was applied in the 6th leaf phase (BBCH 16). The size of the experimental fields was 5 ha. As in the case of the pot experiments, 14 days after the foliar fertilization treatment, the biometric features of 20 randomly selected plants from each experiment object were measured. The maize harvest was carried out on 5 to 20 November in all areas, and then the grain yield and its moisture were determined.

2.5. Analysis of Raw Materials and Plants

To dissolve mineral components, samples of calcined bone and plants were contacted with concentrated acids. Calcined bone was digested using 70% HClO₄ in mineralizator Tecator (FOSS, Hilleroed, Denmark) using the following temperature scheme: 165 °C by 2 h, 200 °C 2.5 h⁻¹, 210 °C
0.5 h$^{-1}$, and 230 °C 1 h$^{-1}$. The plants were digested using acids mixture composed of concentrated acids (HNO$_3$:HClO$_4$:H$_2$SO$_4$) in a ratio of 20:5:1 using mineralizer Tecator with the following temperature scheme: 70 °C by 1.0 h, 105 °C by 1.0 h, 120 °C by 1.0 h, 160 °C by 2.0 h, 167 °C by 2.0 h, and 200 °C by 1.0 h.

The samples of the product were analyzed using an AAS Hitachi Z-2000 (Hitachi, Tokyo, Japan) for the determination of Fe, Mn, Zn, Cu, Ca, Mg, K and Na. The content of phosphorus was determined in solution generated by digestion process, according to the vanadium-molybdenum method [20]. The concentration of phosphorus was determined using a colorimetric assay, based on the formation of colored complexes that form orthophosphate ions in the presence of vanadium and molybdenum ions. The measurements were performed using a spectrophotometer Shimadzu UV-2600 at a wavelength of 435 nm.

Analysis of the ions was conducted using system DIONEX 5000+ HPIC (Thermo Fisher Scientific, Sunnyvale, USA). The prepared solutions of the foliar fertilizers were filtered through syringe filters. The parameters of anions analysis were as follows: the column Dionex AS9 HC 250 × 4 mm and a protective column Dionex AG 50 × 4 mm, flow rate 1 cm$^3$ min$^{-1}$; column oven temperature—30 °C, suppressor ASRS 4 mm, current 45 mA. As the eluent, a 18 mM solution of Na$_2$CO$_3$ was used. The injection volume was 25 µL. The concentration of cations was determined using Dionex CS 16250 × 5 mm column and a Dionex CG16 50 × 5 mm protective column. The flow rate was 1.4 cm$^3$ min$^{-1}$; column oven temperature was 40 °C, suppressor CSRS 4 mm, and current was 123 mA. As the eluent, a 30 mM solution of methanosulfonic acid was used. The injection volume was 5 µL. The temperature of the detector was 40 °C. The quantitative analysis was based on standard curves prepared by injecting a series of standards.

2.6. Statistical Analysis

The statistical analysis of the obtained results was conducted using the program Statistica, version 13.1 (StatSoft Inc., Washington, DC, USA). The significance of the impact of the tested doses of foliar fertilizer on the dry matter of the aboveground parts of the plant, the dry mass of roots of maize plants and the maize yield obtained was evaluated by the analysis of variance, determining the half-confidence intervals by the NIR test at the significance level $\alpha = 0.05$.

3. Results and Discussion

3.1. The Solubilization Procedure of Minerals from Calcined Bones

A number of research teams have been engaged in developing methods to reclaim phosphorus from different sources. The most basic approach is the solubilization of phosphorus compounds and then selective isolation, e.g., by means of struvite precipitation [21,22]. Phosphorus, in this form, may be utilized as a fertilizer. These technologies provide fertilizers that can be applied directly to soil. However, there is also an important class of fertilizers applied in the form of foliar spraying. In the available literature data, there is no information about utilization of foliar fertilizers that were produced from waste, such as sewage sludge, or from animal production. In particular, the animal waste from slaughterhouses such as animal bones are rich in phosphorus, which can be found in the form of hydroxyapatites, e.g., Ca$_{10}$(PO$_4$)$_6$(OH)$_2$. Besides phosphorus, the main element present in these minerals is calcium. The bones from slaughterhouses are a hazardous waste which needs to be further processed. One of the technologies utilized for the treatment of the bone waste is thermal processing. High temperatures in the range of 850–950 °C cause its total mineralization. The minerals, after that treatment, become an attractive source of different elements including phosphorus that could be used as fertilizer. The composition of the waste obtained after thermal processing was summarized in Table 1.

It was observed, that the raw material is rich in various elements that can be used by plant organisms. There is over 17% of phosphorus present as pure P and a number of other elements such as
Ca, Fe, Mn, Zn or Cu. These elements are often found in various fertilizers [23]. However, it remains challenging to transfer these elements in their soluble forms. The utilization of sulfuric acid, for the extraction of phosphorus from hydroxyapatites results in the generation of CaSO₄, i.e., the so called phosphogypsum. It is also possible to use hydrochloric acid solution for phosphorus solubilization. However direct fertilization using this solution is impossible due to the high content of Cl⁻ ions, which cause soil salinity [12,24]. After screening of acids solution which could be potentially used for the extraction of phosphorus, we found that the amount of reclaimed minerals was satisfactory only in the case of nitric acid. The reaction mixture was prepared as: 25 g of bone waste, 120 g of water, and 42 g of nitric acid at the concentration of 65%. In fact, it was possible to solubilize 95% of bone waste material. The solution which contained most of the elements present in bone waste was later concentrated using distillation under reduced pressure. Next, the solution was dried at 60 °C under a pressure of 0.001 MPa and, as a result, a solid substance in the form of a paste was produced. The composition of the soluble fraction was determined, and the results are summarized in Tables 3 and 4.

It was shown that 75% of the elements present in bone waste was transferred into the soluble fraction. The efficiency of the process was determined according to Equation (1):

$$SF (\%) = \frac{(m_{SF} - m_{HNO_3}) \cdot 100}{m_{BW}}$$  (1)

where SF refers to the content of the soluble fraction, mSF refers to the mass of soluble fraction (g), mHNO₃ refers to the mass of nitric acid (V) (g) and mBW refers to the mass of bone waste (g).

The rate of the waste recovery is satisfactory taking into account that the waste bone consisted of hydroxyapatite but also carbonates, which, as a result of the reaction with nitric acid, convert to carbon dioxide. Hydroxyapatite during the reaction with nitric acid converts mainly to calcium nitrate and calcium dihydrogen phosphate according to following reaction (2):

$$\text{Ca}_{10}(\text{OH})_2(\text{PO}_4)_6 + 14\text{HNO}_3 \rightarrow 7\text{Ca(NO}_3)_2 + 3\text{Ca(H}_2\text{PO}_4)_2 + 2\text{H}_2\text{O}$$  (2)

These compounds are well-known components of various fertilizers. It is obvious that the introduction of microelements and macroelements at a certain stage of plant development results in the improvement in their survivability and growth rate. Most fertilizers include a number of components, such as Fe, Mn, Zn, Cu, Mg, Ca or K. These elements were also detected in the obtained product, which is presented in Table 3. The composition of the soluble fraction is presented as a mean value (±SD) for not less than three experiments. Moreover, the obtained product is rich in valuable anions such as nitrates and phosphates, which are the source of the phosphorus (Table 3).

3.2. Pot Experiments

Foliar fertilizing is a key element of intensive plant production, which enables the supply of nutrients under conditions of difficult uptake from the soil and in phases of great demand [25,26] and is characterized by the high production efficiency of elements introduced in this way [24].

The observed high effectiveness of the tested fertilizer applied at relatively low doses (35.4 mg pot⁻¹) probably stems from the beneficial proportions of microelements and macroelements, characteristic for living organisms, which were isolated from natural resources of animal origin. As a consequence, foliar application of the tested fertilizer had impact on the production efficacy of plants during the initial stages of development, and thus the plants were more immune to biotic and abiotic stress factors. The utilized doses of the foliar fertilizer during the pot experiments had an impact on the dry mass of both the aboveground underground parts of the maize plant. The mass of these parts of the maize plant increases with an increasing dose of the fertilizer (Table 5). The highest, 19.6%, increase in the dry mass of the aboveground parts of the maize plant in comparison to the control plants was observed in the case where the fertilizer dose was 35.4 mg pot⁻¹ (3.0 kg ha⁻¹). The utilization of that
dose also resulted in a high dry mass of the underground parts of the plants of the maize plant, which amounted to approximately 1.21 g per plant and was twice as high for plants without foliar fertilizing. An increase in the biomass production determined by the total plant dry mass as a result of fertilization with phosphorus was also observed by other authors [27].

| Table 5. Biometric features of the maize plants 14 days after foliar fertilization. |
|---------------------------------------------------------------|
| **Fertilizer Dose mg pot⁻¹** | **Relative Amount of Chlorophyll (SPAD)** | **Dry Mass of the Aboveground Parts of the Plant g Plant⁻¹** | **Dry Mass of the Underground Parts of the Plant g Plant⁻¹** |
| 0 | 37.20 a | 12.10 a | 0.63 a |
| 11.8 | 39.30 b | 12.39 a | 0.86 b |
| 23.6 | 39.63 c | 14.27 b | 0.93 c |
| 35.4 | 45.20 d | 14.47 c | 1.21 d |

Note. a, b, c—means within rows with different letters differ significantly at \( p \leq 0.05 \).

Plant growth is dependent on physiological processes and in particular on the photosynthesis process. The determination of the amount of the chlorophyll within plant leaves is one of the methods which can be utilized for the evaluation of various factors that have an impact on the plant, i.e., the composition of fertilizers applied onto the plant leaves [24]. The conducted measurements of the relative amount of chlorophyll in the maize plant leaves showed the statistically significant differences between the chlorophyll amounts in plants exposed to various doses of the tested fertilizer (Table 5). The flag leaves of the maize plants fertilized with the various doses of the fertilizer had a statistically significant higher amount of chlorophyll in comparison to the plants grown in the control objects. The highest increase in the plant parameters was observed in the plants fertilized with a fertilizer dose of 35.4 mg pot⁻¹ (3.0 kg ha⁻¹). The relative amount of chlorophyll in the maize plant leaves fertilized with such a dose of the fertilizer increased by 21.5% in comparison to the plants grown in the control vases.

The foliar application of microelements and macroelements in the tested fertilizer (Table 3) counteracted the deficiencies of nutrients, which were observed on the plants grown in the control vases. Better supply of nutrients to the fertilized plants improved their vigor and resistance to stress factors, which in turn resulted in an increased mass of roots and the aboveground parts of the plant and better physiologic parameters (Tables 5 and 6).

| Table 6. Content of selected microelements and macroelements in the aboveground and underground parts of the maize plant 14 days after foliar fertilization. |
|---------------------------------------------------------------|
| **Fertilizer Dose mg pot⁻¹** | **P** | **Ca** | **K** | **Na** | **Mg** | **Fe** | **Mn** | **Zn** | **Cu** |
| Underground Parts of the Plant | g kg⁻¹ | mg kg⁻¹ | | | | | | | |
| 0 | 0.19 a | 1.66 a | 4.53 b | 0.98 b | 0.64 a | 167.16 c | 102.54 d | 25.88 a | 4.40 a |
| 11.8 | 0.22 b | 2.11 c | 3.97 a | 0.98 b | 0.71 c | 171.05 d | 74.01 b | 39.75 c | 6.61 c |
| 23.6 | 0.28 d | 1.83 b | 4.67 c | 0.88 a | 0.66 b | 171.54 a | 55.87 a | 33.33 b | 5.86 b |
| 35.4 | 0.25 c | 2.57 d | 4.85 d | 1.28 c | 0.88 d | 115.84 b | 81.68 c | 50.67 d | 7.32 d |

Note. a, b, c—means within rows with different letters differ significantly at \( p \leq 0.05 \).
3.3. Field Experiments

The results from the field experiments in selected locations (Figure 1, Table 2) confirmed the statistically significant effect of the dose of 3.0 kg ha\(^{-1}\) of the tested foliar fertilizer on plant growth and the dry mass of aboveground parts of the maize plant and roots of the maize plant on the 14th day after application of foliar fertilization. The plants fertilized with the tested fertilizer were higher than 40.5\% (location C) to 154.8\% (location D) compared to the plants from control objects. The foliar application of the fertilizer caused an increase in the dry biomass of the aboveground parts of plants, which on average was higher by 75.5\% in comparison to the plants that were not fertilized with foliar fertilizer. The dry mass of the underground parts of plants fertilized was higher from plants from control facilities by 81.4\%.

In literature there are reports about a several percent increase in crop yields as a result of foliar fertilization, in particular for solutions of poly compound mixtures and micronutrient fertilizers [28–30]. Also, the growth time can be reduced and therefore it is possible to harvest crops earlier [31]. In the field experiments, the applied dose of the tested foliar fertilizer, independent of meteorological conditions as well as the soil conditions, resulted in an increased maize grain yield on average from 4.2\% (location C) to 7.3\% (location B) in comparison to yields obtained without foliar fertilization. The foliar fertilizer tested in the indicated locations resulted in, on average, a 5.1\% increase in the final yield of grain in comparison to the yield of plants without foliar fertilization (Table 7).

| Location | Fertilizer Dose kg ha\(^{-1}\) | Biometric Features of Maize Plant | Maize Grain ha\(^{-1}\) |
|----------|-------------------------------|---------------------------------|----------------------|
|          | Plants Highem Plant\(^{-1}\)  | Dry Mass of the Aboveground Parts of the Plant g Plant\(^{-1}\) | Dry Mass of the Underground Parts of the Plant g Plant\(^{-1}\) | Maize Grain ha\(^{-1}\) |
| A        | 0 3.0 | 0 3.0 | 0 3.0 | 0 3.0 |
| B        | 184.0 a 207.3 b | 80.1 a 117.8 b | 62.3 a 117.8 b | 13.4 a 14.0 b |

Note. a, b, c—means within rows with different letters differ significantly at \(p \leq 0.05\).

4. Conclusions

The utilization of a nitric acid solution for the solubilization of minerals from animal bones provided a solution rich in N-NO\(_3\), PO\(_4^{3-}\) and macro- and microelements of high fertilization value. The isolates have been successfully used as foliar fertilizers in the cultivation of maize plant. The application of a fertilizer dose of 3 kg ha\(^{-1}\) had a positive impact on both aboveground and belowground parts of maize and the physiological parameters in the initial stage of plant development.

The fertilizer tested in field experiments with boron and molybdenum compounds confirmed the effectiveness of the fertilizing effect in various soil and climatic conditions in maize cultivation by increasing the biometric features of plants in the initial phase of their growth and development, as well as the increase in maize grain production (on average, by 600 kg ha\(^{-1}\)).
