ABSTRACT

We show that the detection of acoustic oscillations in both upcoming cosmic microwave background (CMB) satellite experiments and large-redshift surveys can yield 5% determinations of $H_0$ and $\Omega_m$, an order-of-magnitude improvement over CMB data alone. CMB anisotropies provide the sound horizon at recombination as a standard ruler. For reasonable baryon fractions, this scale is imprinted on the galaxy power spectrum as a series of spectral features. Measuring these features in redshift space determines the Hubble constant, which in turn yields $\Omega_m$ once combined with CMB data. Since the oscillations in both power spectra are frozen-in at recombination, this test is insensitive to low-redshift cosmology.

Subject headings: cosmic microwave background — cosmology: theory — dark matter — large-scale structure of universe

1. INTRODUCTION

In the usual cosmological paradigm, the cosmic microwave background (CMB) contains a vast amount of information about cosmological parameters (Hu, Sugiyama, & Silk 1997). With upcoming experiments, most notably the two satellite missions Microwave Anisotropy Probe (MAP) and Planck, detailed measurements of the angular power spectra of its anisotropy and polarization may accurately determine many cosmological parameters (Jungman et al. 1996; Bond, Efstathiou, & Tegmark 1997; Zaldarriaga, Spergel, & Seljak 1997). However, certain changes in the cosmological parameters can conspire to leave the CMB power spectra unchanged, resulting in degenerate directions in the parameter space (Bond et al. 1994, 1997; Zaldarriaga et al. 1997; Hu et al. 1998). For example, since the Hubble constant $H_0$ and the matter density $\Omega_m$ can be varied while keeping the angular diameter distance and the matter-radiation ratio fixed, their values remain uncertain but highly correlated. Such degeneracies must be broken with cosmological information from other sources.

Upcoming redshift surveys for the study of large-scale structure hold the potential for resolving this issue. In particular, the 2dF survey and the Sloan Digital Sky Survey (SDSS) should measure the galaxy power spectrum on large enough scales to allow detailed comparisons with the mass power spectrum predicted by cosmological theories. In this Letter and a companion paper (Eisenstein, Hu, & Tegmark 1998b, hereafter EHT), we explore the potential of combining redshift surveys and CMB anisotropy data for the purpose of parameter estimation. Here we focus on the dramatic improvement possible and CMB anisotropy data for the purpose of parameter estimation. In this Letter and a companion paper (Eisenstein, Hu, & Tegmark 1998b, hereafter EHT), we explore the potential of combining redshift surveys and CMB anisotropy data for the purpose of parameter estimation. We show that the detection of acoustic oscillations in both upcoming cosmic microwave background (CMB) satellite experiments and large-redshift surveys can yield 5% determinations of $H_0$ and $\Omega_m$, an order-of-magnitude improvement over CMB data alone. CMB anisotropies provide the sound horizon at recombination as a standard ruler. For reasonable baryon fractions, this scale is imprinted on the galaxy power spectrum as a series of spectral features. Measuring these features in redshift space determines the Hubble constant, which in turn yields $\Omega_m$ once combined with CMB data. Since the oscillations in both power spectra are frozen-in at recombination, this test is insensitive to low-redshift cosmology.

2. METHODOLOGY

We seek to quantify the potential sensitivity of these data sets to various cosmological parameters. For this, we use the Fisher matrix formalism (see Tegmark, Taylor, & Heavens 1997 for a review), which yields a lower limit on the statistical errors on cosmological parameters achievable by a set of experiments. This formalism operates within the context of a parameterized cosmological model. For this, we use a 12-variable parameterization of the adiabatic cold dark matter (CDM) model, described in detail in EHT. It includes CDM, baryons, massive neutrinos, a cosmological constant $\Lambda$, curvature ($\Omega_k$), a reionization optical depth, and a primordial helium fraction. It assumes an initial scalar power spectrum $P(k) \propto k^{n_s} a^{2} \log(1/a_{*})$ with tilt $n_s$, a logarithmic running of the tilt $\alpha$, and an unknown amplitude as well as scale-invariant tensor contributions with an unconstrained amplitude. Finally, it allows an unknown linear bias to adjust the galaxy power spectrum relative to the mass $P_{gal} = b^2P_{mass}$. All of the above parameters are determined simultaneously from the data.

For CMB anisotropies, we use the experimental specifications of the MAP and Planck satellites for temperature and polarization (EHT). We assume that foregrounds and systematics can be eliminated with negligible loss of cosmological information. For large-scale structure, we use the projected specifications of the bright red galaxy (BRG) sample of the SDSS to determine its sensitivity to the linear power spectrum (Tegmark 1997). On small scales, the observed power spectrum reflects nonlinear effects and galaxy formation issues. We therefore employ only wavenumbers less than $k_{max} = 0.1$ h Mpc$^{-1}$, under the assumption that the linear power spectrum on these scales can be reconstructed (up to the unknown linear bias)
The errors will be difficult to detect. Changes that affect large angles while leaving the acoustic peaks unchanged will be difficult to detect.

The angular diameter distance $d_A$ to the last scattering surface contains the most important degeneracy for the present discussion. The CMB acoustic peaks are a high-redshift pattern viewed at distance $d_A$. The pattern may be held fixed by keeping $\Omega_b h^2$ and the baryon density $\Omega_b h^2$ constant. However, $d_A$ depends on the low-redshift effects of a cosmological constant or curvature. Changing $\Omega_b$ and $\Omega_b$ so as to keep the angular diameter distance constant leaves the acoustic peaks unchanged. Only large-angle ($\ell \approx 50$) gravitational redshift effects or small-angle ($\ell \approx 1000$) gravitational lensing effects can resolve this ambiguity.

In short, the CMB data sets will yield precision information on the physical properties at high redshift, notably, $H_0$, $\Omega_b h^2$, $\Omega_b h^2$, and $d_A(\Omega_b h^2, \Omega_b, \Omega_m)$, but not on $H_0$ and $\Omega_b$ individually. A similar situation occurs in quintessence models with trade-offs between $\Omega_b$ and the equation of state of the $Q$-field (Huey et al. 1998).

In Table 1, we present the error bars on $H_0$ and $\Omega_b$ attainable by upcoming CMB satellite experiments within our 12-dimensional parameter space. One sees that when varying both $\Omega_b$ and $\Omega_b$, the constraints on $H_0$ and $\Omega_b$ are poor, although the polarization information does provide considerable help. Even if one assumes a flat cosmological model ($\Omega_b = 0$), MAP, with its partial coverage of the acoustic peaks, will not yield tiny errors on $H_0$ and $\Omega_b$.

There are several caveats. The Fisher matrix expansion of the likelihood function is not accurate for large steps in parameter space, which means that large error bars accurately detect a degenerate direction but may inaccurately reflect its magnitude (Zaldarriaga et al. 1997). One artifact of this is that the ellipses in Figure 1 follow straight lines rather than curves (e.g., constant $\Omega_b h^2$ in the CMB case). Moreover, the errors are slightly overestimated in the case of Planck because we have not included gravitational lensing (Seljak 1996; Metcalf & Silk 1997), by which the differences in growth factor between otherwise degenerate models will alter the small-angle power spectra. Nevertheless, the point remains that the CMB alone will not constrain $H_0$ and $\Omega_b$ to a level capable of strong consistency checks against other cosmological tests.

4. RESULTS WITH REDSHIFT SURVEYS

4.1. Linear Analysis

When we include the Fisher information matrix from SDSS, the error bars on $H_0$ and $\Omega_b$ drop by an order of magnitude. In Table 1, we see that for a fiducial $\Lambda$CDM model, the errors on $H_0$ are below 3 km s$^{-1}$ Mpc$^{-1}$ while those on $\Omega_b$ are around 0.035. EHT discuss improvements on other parameters of the model; however, none are nearly as dramatic. Figure 1 displays the situation. Note that the results are roughly independent of whether polarization information is available or not.

The reason for this dramatic improvement lies with the baryons. Table 2 shows the error bars on $H_0$ for a sequence of fiducial models with increasing baryon fraction; those on $\Omega_b$ behave similarly. Increasing the baryon fraction from $\sim 1\%$ to $\sim 15\%$ results in a dramatic increase in the information provided by SDSS. A baryon fraction exceeding $10\%$ is strongly indicated by cluster gas fractions (White et al. 1993; David, Jones, & Forman 1995; White & Fabian 1995; Evrard 1997).

As the baryon fraction increases, significant acoustic oscillations develop in the matter power spectrum (see Fig. 2, Hu & Sugiyama 1996, and Eisenstein & Hu 1998a). There is a characteristic scale of these oscillations that is known as the sound horizon; morphologically, the power spectrum acquires a sharp break near the sound horizon and a series of oscillations marking the harmonics of this scale. The size of the sound horizon can be calculated given knowledge of the physical conditions at high redshift, particularly $\Omega_b h^2$ and $\Omega_b h^2$. Since

![Table 1](https://example.com/table1.png)

**Table 1** Errors on $H_0$ and $\Omega_b$ for $\Lambda$CDM

| Experiment                     | $\Delta H_0$ | $\Delta \Omega_b$ |
|--------------------------------|--------------|-------------------|
| MAP (no polarization)          | 1.3          | 0.1              |
| With SDSS                      | 2.0          | 0.2              |
| MAP (with polarization)        | 2.5          | 0.3              |
| With SDSS                      | 3.0          | 0.4              |
| Planck (no polarization)       | 3.5          | 0.5              |
| With SDSS                      | 4.0          | 0.6              |
| Planck (with polarization)     | 4.5          | 0.7              |
| With SDSS                      | 5.0          | 0.8              |

Note.—The fiducial model has $\Omega_b = 0.35$, $H_0 = 65$ km s$^{-1}$ Mpc$^{-1}$, and $\Omega_b = 0.05$. We use $k_{\text{max}} = 0.1$ h Mpc$^{-1}$ for SDSS. Errors are 1 $\sigma$, $\Delta H_0$ errors are in units of km s$^{-1}$ Mpc$^{-1}$. General: $\Omega_b$ estimated from data. Flat: $H_0 = 0$ by fiat.

![Figure 1](https://example.com/fig1.png)

**Figure 1**—The 68% allowed regions for MAP (with polarization) alone, SDSS ($k_{\text{max}} = 0.1$ h Mpc$^{-1}$) alone, and the two combined. The lines in the directions of constant $\Omega_b h^2$, $\Omega_b h$, and $\Omega_b h^2$ are shown.

![Table 2](https://example.com/table2.png)

**Table 2** Errors on $H_0$ as Function of $\Omega_b$

| $\Omega_b$ | $\Omega_b/\Omega_m$ (%) | MAP (with polarization) | With SDSS |
|------------|-------------------------|-------------------------|-----------|
| 0.005      | 1.4                     | 36                      | 12        |
| 0.02       | 5.7                     | 29                      | 9.2       |
| 0.05       | 14                      | 23                      | 2.9       |
| 0.10       | 29                      | 24                      | 1.3       |

Note.—Same parameters as in Table 1 save for the baryon fraction.
these are exactly the quantities that are well constrained by the relative heights of the CMB acoustic peaks, we can accurately infer the scale of these features in real space. Its measurement in the redshift-space power spectrum then yields an accurate measure of $H_0$.

At low baryon fractions, the SDSS power spectrum still reduces the error bars on $H_0$ and $\Omega_m$. This results from the one scale left in the matter power spectrum, that of the horizon at matter-radiation equality. In redshift space, this yields a measure of $\Gamma \equiv \Omega_m h^2$, with considerable inaccuracies due to confusion with scalar tilt. However, the fact that the SDSS ellipse in Figure 1 lies along a line very different from constant $\Omega_m h^2$ indicates that at moderate baryon fractions, this feature is not providing the primary leverage on $H_0$. Note that the break and oscillation morphology of the baryonic features cannot be mimicked by the effects of tilt or massive neutrinos.

In short, baryonic features yield a standard ruler, whose length can be accurately inferred by the CMB and can be measured in redshift space using large-redshift surveys. The comparison of lengths yields $H_0$; combining this with $\Omega_m h^2$ gives $\Omega_m$. This inference is independent of the angular diameter distance to last scattering (provided that the peaks are visible at all!), so this method will function regardless of cosmological constant, spatial curvature, or more exotic smooth components (see, e.g., Turner & White 1997). With $\Omega_m$ known, the location of the CMB peaks and the information from Type Ia supernovae (Perlmutter et al. 1998; Riess et al. 1998) may be focused on distinguishing these low-redshift effects (Tegmark et al. 1998a; Hu et al. 1998).

### 4. Nonlinearities

Baryonic oscillations are a feature of the linear power spectrum. Nonlinear evolution erases these signatures. Hence, we should test the extent to which the above results depend upon our use of linear theory.

Hereinafter, we have assumed that we could use the linear power spectrum on scales longward of $k_{\text{max}} = 0.1 \text{ Mpc}^{-1}$. This is close to the point at which nonlinearities will smooth the oscillations. We therefore display in Table 3 the effect of altering $k_{\text{max}}$, again simply ignoring information on all smaller scales. For several fiducial models, we find that moving $k_{\text{max}}$ from 0.1 to 0.2 $\text{ Mpc}^{-1}$ decreases the errors on $H_0$ and $\Omega_m$ by about a factor of 2.5. However, these gains saturate as one extends $k_{\text{max}}$ to 0.4 $\text{ Mpc}^{-1}$; the acoustic oscillations there are of such small amplitude that little information is gained.

We also consider an alternative formulation in which we model the matter power spectrum by a fitting formula (Eisenstein & Hu 1998b) that includes the break at the sound horizon but not the oscillations. The resulting errors are shown in Table 3. For $k_{\text{max}} \approx 0.08 \text{ Mpc}^{-1}$, the performance is significantly worse than that achieved with the actual linear power spectrum. This is close to the location of the first bump in this fiducial model. Note that including the featureless power spectrum on scales from 0.1 to 0.4 $\text{ Mpc}^{-1}$ adds very little additional information on $H_0$ or $\Omega_m$.

We therefore conclude that detection of at least the first of the acoustic oscillations ($k \approx 0.07 \text{ Mpc}^{-1}$ in this model) is critical to enabling a precision measure of $H_0$ and $\Omega_m$. Detecting additional peaks improves the possible error bars, but with diminishing returns, because the oscillations damp down in amplitude. In Figure 2, we present the results of second-order perturbation theory for the power spectrum (Jain & Bertschinger 1994) assuming a linear power spectrum normalization of $\sigma_8 = 1.0$. For this value, linear theory indeed holds to $k_{\text{max}} \approx 0.1 \text{ Mpc}^{-1}$, so that the first baryonic peak survives while higher peaks are smeared out. The second-order correction scales as $\sigma_8^2$; note that a linear $\sigma_8 = 1.0$ would yield an observed (nonlinear) value well in excess of unity. Cosmological simulations normalized to the cluster abundance reach similar conclusions (Meiksin, Peacock, & White 1998).

### 5. Discussion

Detection of acoustic oscillations in the matter power spectrum would be a triumph for cosmology, since it would confirm the standard thermal history and the gravitational instability paradigm. Moreover, because the matter power spectrum displays these oscillations in a different manner than does the CMB, we would gain new leverage on cosmological parameters. In particular, we have shown in this Letter that the combination of power spectrum measurements from a galaxy redshift survey with anisotropy measurements from CMB satellite experiments could yield a precision measurement of $H_0$ and $\Omega_m$.

The potential measurement of $H_0$ and $\Omega_m$ depends critically on the ability of the redshift survey to detect the baryonic features in the linear power spectrum. The best possible error

### TABLE 3

| $k_{\text{max}}$ | $\Delta H_0$ | $\Delta \Omega_m$ |
|------------------|--------------|------------------|
|                  | $P(k)$       | $P_d(k)$         | $P(k)$ | $P_d(k)$ |
| MAP alone        | 23           | 23               | 0.25   | 0.25     |
| 0.025            | 15           | 15               | 0.17   | 0.16     |
| 0.05             | 9.7          | 10.7             | 0.098  | 0.11     |
| 0.1              | 2.9          | 10.0             | 0.037  | 0.11     |
| 0.2              | 1.2          | 9.0              | 0.016  | 0.10     |
| 0.4              | 0.9          | 8.6              | 0.014  | 0.10     |

Note.—MAP with polarization has been taken in each case. Limits with the actual linear power spectrum $P(k \lesssim k_{\text{max}})$ are compared with those from a smoother analytic form $P_d(k \lesssim k_{\text{max}})$ (see text). Same model and notation as in Table 1.
bars are a strong function of the baryon fraction but are surprisingly good even if the fraction is \(~10\%\), roughly the minimum implied by cluster observations. For such cases, the fractional limits achievable with the SDSS are 5\% for \(H_0\) and 10\% for \(\Omega_m\), if only the first acoustic peak in \(P(k)\) is detected. Detecting the smaller scale peaks could allow an additional factor of 3 refinement; the exact limits would depend on the scale at which nonlinear effects smooth out the power spectrum. The results depend only mildly on the details of the CMB experiment: we find only slight gains as our presumed CMB data set improves from \textit{MAP} without polarization to \textit{Planck} with polarization. While we have quoted numbers for SDSS, it is possible that the 2dF survey will be able to make significant progress on the detection of features in the power spectrum on very large scales. Unfortunately, the hints of excess power on 100 \(h^{-1}\) Mpc scales are not likely to be due to baryons (Eisenstein et al. 1998a).

We have treated the galaxy power spectrum by assuming linear bias on large scales. There is some theoretical motivation for this (Scherrer & Weinberg 1997); moreover, if bias tends toward unity as structure grows (Fry 1996; Tegmark & Peebles 1998), then scale dependences in the bias at the time of formation will be suppressed. Most importantly, this method of measuring \(H_0\) and \(\Omega_m\) depends on extracting an oscillatory feature from the power spectrum. While one cannot prove that scale-dependent bias should be monotonic on the largest scales, this seems more likely than an oscillation! Finally, the assumption of linearity can be tested by constructing the power spectrum with different types of galaxies (see, e.g., Peacock 1997); future redshift surveys will allow this to be done on very large scales with good statistics.

The method proposed here yields \(H_0\) independent of local distance measurements and \(\Omega_m\) without the complications inherent in dynamical methods; i.e., this method is free of many confusing astrophysical problems. On the other hand, it does depend on restricting oneself to a class of models with observable acoustic oscillations in both CMB anisotropies and the galaxy power spectrum. This assumption will be definitively tested from the data itself.

If the method described in this Letter can yield tight constraints on \(H_0\) and \(\Omega_m\), it will then be very important to compare these with other measurements of these quantities. In the coming decade, there will be a number of paths toward a precision measure of \(H_0\), such as the local distance ladder (see, e.g., Freedman et al. 1998), gravitational lensing (see, e.g., Blandford & Kundic 1997), and the Sunyaev-Zeldovich effect (see, e.g., Cooray et al. 1998). Similarly, good estimates of \(\Omega_m\) may be possible from velocity fields (see, e.g., Dekel 1997), cluster evolution (Carlberg et al. 1997a; Bahcall, Fan, & Cen 1997), and \textit{MIL} measurements (see, e.g., Carlberg, Yee, & Ellingson 1997b). If the results from these diverse sets of measurements are found to agree, we will have a secure foundation on which to base our cosmology.

Numerical power spectra were generated with CMBFAST (Seljak & Zaldarriaga 1996). We thank Martin White for useful discussions. D. J. E. is supported by a Frank and Peggy Taplin Membership; D. J.
