ABSTRACT

The nearby barred spiral galaxy NGC 1672 shows dramatic starburst activity and may also host a Seyfert 2 nucleus. We present new X-ray observations that set constraints on starburst and Seyfert activity in NGC 1672. Two ROSAT HRI exposures, taken in 1992 and 1997, are used to investigate long-term variability of the known X-ray sources and to search for new sources of X-ray emission. We find large-amplitude (≈69%) variability from X-3, one of the off-nuclear sources located near an end of the galactic bar. X-3 has a peak observed 0.2–2.0 keV luminosity of $\approx 2.5 \times 10^{39}$ ergs s$^{-1}$, and it is probably a luminous X-ray binary or young supernova remnant. We do not observe variability of the nuclear source X-1 or the strong off-nuclear source X-2. Our analyses also reveal two new off-nuclear sources, one of which is associated with a bright region along a spiral arm, and we find evidence for large-scale diffuse X-ray emission throughout part of the disk of NGC 1672. Furthermore, we use ASCA data taken in 1995 to constrain the hard X-ray properties of NGC 1672. While the nuclear source X-1 is the dominant soft X-ray source in NGC 1672, we find that the bulk of the 2–10 keV and 5–10 keV emission is spatially coincident with the off-nuclear source X-3, giving it an apparent 0.2–8 keV luminosity of $\geq 6 \times 10^{39}$ ergs s$^{-1}$. A power-law–plus–Raymond-Smith model provides an acceptable fit to the full-band ASCA spectra. We do not find any evidence for a luminous but absorbed nuclear X-ray source. If there is a luminous Seyfert 2 nucleus in NGC 1672, it must be obscured by a “Compton-thick” torus with a column density of $\geq 2 \times 10^{24}$ cm$^{-2}$.

Key words: galaxies: individual (NGC 1672) — galaxies: Seyfert — galaxies: starburst — X-rays

1. INTRODUCTION

NGC 1672 is a $V = 10.1$ barred spiral galaxy in the southern hemisphere that is viewed nearly face-on. It shows dramatic nuclear and extranuclear star formation activity, including starburst regions near the ends of its strong bar (see, e.g., Pastoriza 1967; Osmer, Smith, & Weedman 1974; Baumgart & Peterson 1986). It may have a Seyfert 2 nucleus (see, e.g., Véron, Véron, & Zuidervijk 1981; Brandt, Halpern, & Iwasawa 1996, hereafter BHI96), but at present this has not been firmly established. NGC 1672 is at a distance of 16.3 Mpc ($H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$), and the Galactic neutral hydrogen column density in its direction is $N_H = (2 \pm 1) \times 10^{21}$ cm$^{-2}$ (Heiles & Cleary 1979).

X-ray emission is powerful for probing both the endpoints of stellar evolution and Seyfert activity, and NGC 1672 is known to be a prodigious source of X-rays. BHI96 presented a detailed ROSAT Position Sensitive Proportion- al Counter (PSPC) and High Resolution Imager (HRI) study of NGC 1672, and they found several sources of X-ray emission coincident with the galaxy. The nucleus showed the strongest emission. This emission was slightly resolved, suggesting at least some starburst X-ray activity, but, from the ROSAT data, BHI96 were unable to determine whether the bulk of the emission was from a starburst region or hidden Seyfert. Awaki & Koyama (1993) claimed a hard X-ray detection of a $L_{2-10\text{keV}} \approx 10^{41}$ ergs s$^{-1}$ Seyfert nucleus with the Ginga Large Area Counter (LAC), but concerns about source confusion were present (the LAC was a nonimaging detector and had a 2" × 4" field of view).

In addition to the nuclear X-ray emission, BHI96 also found luminous X-ray sources coincident with the starburst regions near the ends of the galactic bar. It was difficult to determine the nature of these sources because of limited photon statistics. They could be consistently modeled as superbubbles, collections of X-ray binaries, or “super-Eddington sources” (see, e.g., Fabbiano 1998).

To investigate the X-ray properties of NGC 1672 further, we performed a second ROSAT HRI observation of it in 1997. Our goals for this observation were (1) to study the long-term X-ray variability properties of the currently known sources, (2) to search for new X-ray sources that were not detected before because of their variability, and (3) to obtain better photon statistics for investigation of any weak point sources or large-scale diffuse X-ray emission. Here we present the results from our second HRI observation, as well as an improved analysis of the original 1992 HRI observation. We also use ASCA data from 1995 to constrain the hard X-ray properties of NGC 1672.

2. ROSAT HRI OBSERVATIONS, DATA REDUCTION, AND ANALYSIS

2.1. Observations and Basic Analysis

NGC 1672 was observed with the ROSAT HRI (see, e.g., David et al. 1999) during the period 1997 January 27 to

ACTIVITY IN NCG 1672

1997 March 2 (35.0 ks exposure time). The observation went smoothly, and reduction and analysis of the data were performed with the ASTERIX software system (Allan & Vallence 1995). We created three images for subsequent analysis: (1) an image from the 1997 HRI observation, (2) an image from the original 1992 HRI observation (24.5 ks; see BHI96), and (3) a “combined” image using the data from both the 1992 and 1997 observations (59.5 ks total exposure time). All images were made with 2″ pixel⁻¹ resolution so that the HRI point-spread function (PSF) was oversampled by a factor of ≈2. We also used only HRI channels 3–8, since this channel range provides maximum sensitivity for detecting point sources and low surface brightness diffuse emission (see §3.4 of David et al. 1999).

2.2. Point-Source Searching, Parameterization, and Variability

The three images described in §2.1 were analyzed using the point-source searching software PSS (Allan 1995). PSS locates point sources by convolving an HRI image with a position-dependent model for the HRI PSF, and it calculates point-source significances using the Cash (1979) statistic. We used constant backgrounds for each of the three images, and our manual background analyses showed that this is valid in the region around NGC 1672. We consider for further study point sources that are within 2.3 of the center of NGC 1672 (this corresponds to the main optical extent of the galaxy) and are found to be significant at ≥4σ in at least one of the three images. Given these criteria, we expect ≈0.3 false sources in total. PSS also creates a “significance map” showing the HRI image after it has been convolved with the PSF model; we show the significance map for the 1997 observation in Figure 1.

In Table 1 we give (background-subtracted) source counts, mean count rates, fluxes, and luminosities for all sources. We have adopted the source naming convention of BH96 but have also added sources X-7, X-8, and X-9.² Source counts were calculated using circular regions chosen

² Sources X-4 and X-6 of BH96 are omitted from Table 1 and all subsequent discussion because they are outside the main optical extent of the galaxy and the regions of strongest star formation. In addition, X-6 is probably associated with a bright foreground star.
to fit the morphology of each source. When sources were not detected in one of the images, we calculated 3σ upper limits. We used the PIMMS (Mukai 1997) software package to convert the mean count rates for each source into 0.2–2.0 keV fluxes and luminosities. For X-1, we adopted the Raymond-Smith thermal plasma model of BH196 to perform this conversion. For all other sources, we adopted a power-law model with a photon index of Γ = 2 and the Galactic column density.

The 1997 observation has revealed a new probable X-ray source (X-8) within the optical extent of NGC 1672. This source lies near the edge of one of the prominent spiral arms. It is detected at the 4.0σ level, so there is a small but nonnegligible chance that it is caused by a statistical fluctuation. In addition, our analyses of all three images show that the extended source X-3 of BH196 actually appears to be two separate sources (labeled here as X-3 and X-7; see Figs. 1–2). This difference between BH196 and our analysis is understandable because our HRI data have been through a revised processing that includes better filtering as well as satellite aspect information from the ROSAT Wide Field Camera (M. Corcoran 1998, private communication). These factors improve the spatial resolution. In addition, BH196 used the full HRI band, while we use only channels 3–8 (see §2.1). Finally, searching the 59.5 ks combined image reveals another new point source, X-9 (see Fig. 2). This X-ray source is spatially coincident with a bright region along one of the spiral arms that contains three large H II regions (numbers 31, 34, and 39 in Table 2 of Evans et al. 1996). The alignment of the X-ray and optical emission supports the reality of the X-ray detection.

To check the X-ray spatial extent results of BH196, we have performed spatial extent analyses for X-1 and X-2 using both the 1992 and 1997 observations. Our results are in general agreement with those of BH196: X-2 does not show any clear evidence for spatial extent, while X-1 is extended on about the scale of the nuclear ring. X-1 is more extended than X-2, and this strongly suggests that its apparent extent is not an artifact of aspect solution variability (see Morse 1994).

We have compared the mean count rates for the 1992 and 1997 observations to search for long-term source variability. X-3 shows significant mean count rate variability with an ≈69% increase between 1992 and 1997. The Poisson probability that this variability is merely caused by a statistical fluctuation is less than 0.5%. We have searched for rapid variability of X-3 within the 1997 data, and we do not find any highly significant variability.

The source X-5, which is thought to be associated with a foreground star (see BH196), also shows significant variability. X-1 and X-2 do not show significant variability. We place upper limits of ≈15% and ≈30% on the variability of X-1 and X-2, respectively.

Table 1

| Source Name | Image | a2000 | δ2000 | Source Counts | Mean Count Rate | FLX | LX |
|-------------|-------|-------|-------|---------------|----------------|-----|-----|
| X-1         | 1992  | 04 45 42.2 | -59 14 50.3 | 174 ± 14.3 | 22.4 | 71.0 ± 5.83 | 20.9 | 7.4 |

|             | 1997  | ...       | <12     | <3.0 | <3.3 | <1.3 | <0.55 |
|             | Comb. | 04 45 29.5 | -59 13 27.3 | 10 ± 5.2 | 4.0 | 1.7 ± 0.9 | 0.70 | 0.29 |

Note—Units of right ascension are hours, minutes, and seconds, and units of declination are degrees, arcminutes, and arcseconds. The 1992 observation had an exposure of 24.5 ks, and the 1997 observation had an exposure of 35.0 ks; the exposure time for the combined ("Comb." ) observation is 59.5 ks. Source positions have errors of ≈0.2. Source counts, source significances (σ), and source mean count rates are calculated using HRI channels 3–8 (see §2.1). We have corrected for this channel range when calculating fluxes and luminosities. FX and LX are listed for the 0.2–2.0 keV band. LX is corrected for Galactic absorption but FX is not. Our source fluxes and luminosities differ from those of BH196 because we use a narrower energy band (0.2–2.0 keV vs. 0.1–2.5 keV) and a smaller distance (16.3 Mpc vs. 22.8 Mpc). In addition, note that we have resolved source X-3 of BH196 into two sources, X-3 and X-7. We have not computed LX for X-5 because we believe this source is associated with a foreground star (see §2.2). X-8 is detected at 3.8σ in the combined observation.
2.3. Diffuse X-Ray Emission

We have used the adaptive kernel smoothing algorithm ASMOOTH (Ebeling, White, & Rangarajan 2000) to search for diffuse X-ray emission in the 59.5 ks combined image. ASMOOTH convolves a Gaussian of variable, position-dependent size with an image to allow detection of spatial structure on a wide range of scales, and it provides a quantitative assessment of the significances of observed features. We find evidence for an area of dimensions \(0.5 \times 1\) of diffuse X-ray emission between X-1 and X-2 (see Fig. 3). We have examined whether this emission can be explained as spillover from X-1 and X-2, and the observed emission appears to exceed that expected from these two sources significantly (even after taking into account reasonable ROSAT aspect solution errors; see Morse 1994). Note that similar emission is not seen between X-1 and X-3, even though these two sources are closer together than X-1 and X-2 (1.1 vs. 1.4 separation). ASMOOTH indicates that the diffuse emission is significant at the \(\approx 3.7\) \(\sigma\) level, and our manual calculations using rectangular regions give similar significances. We estimate \(\approx 40\) counts in total from the diffuse emission, so the count rate is \(\approx 7 \times 10^{-4}\) counts s\(^{-1}\). This emission may be associated with hot, diffuse gas in the interstellar medium of NGC 1672. If we adopt a 0.55 keV Raymond-Smith model with solar abundances and the Galactic column density, we estimate a total 0.2–2.0 keV flux of \(\approx 2 \times 10^{-14}\) ergs cm\(^{-2}\) s\(^{-1}\) and a 0.2–2.0 keV luminosity of \(\approx 6 \times 10^{38}\) ergs s\(^{-1}\) (the flux and luminosity values depend fairly strongly on the unknown abundances of the gas). Of course, we are not able to prove that this emission must be from truly diffuse hot gas. It could also plausibly arise from several weak point sources that are individually below our detection threshold.

3. ASCA Observations, Data Reduction, and Analysis

3.1. Observations and Basic Analysis

NGC 1672 was observed with ASCA (Tanaka, Inoue, &
Holt 1994) on 1995 November 23–24. Both Solid-State Imaging Spectrometer CCD detectors (SIS0 and SIS1) and both Gas Imaging Spectrometer scintillation proportional counters (GIS2 and GIS3) were operated. The SISs were operated in 1 CCD mode, and the GISs were operated in PH mode. We have used the Revision 2 processed data from Goddard Space Flight Center for the analysis below, and we have adopted the standard Revision 2 screening criteria (see Pier 1997). After data screening, the exposure times were 33 ks for SIS0 and SIS1 and 40 ks for GIS2 and GIS3. Data reduction was performed using XSELECT (Ingham & Arnaud 1998).

The spatial resolution of ASCA is a significant limiting factor when studying NGC 1672, so we will present only the main results of our ASCA imaging analysis. The PSFs of the ASCA X-ray Telescopes have half-power diameters of \( \approx 3' \) (compare with Figs. 1–3 and note that X-1 and X-3 are separated by only 1'). However, they also have fairly sharp cores that allow two point sources as close as \( \approx 30' \) to be resolved. In the case of the GISs, the final spatial resolution is worsened somewhat by the detectors’ spatial responses, and the GISs cannot be effectively used to study structure on scales smaller than \( \approx 1' \). For sources observed in an approximately on-axis manner, the ASCA SIS and GIS positional uncertainties are \( \approx 40' \) and \( \approx 50' \), respectively (90% confidence; Gotthelf 1996; E. Gotthelf 1999, private communication).

We have created full (0.6–10 keV for SIS and 1.0–10 keV for GIS), soft (0.6–2.0 keV for SIS and 1.0–3.0 keV for GIS), hard (2–10 keV for SIS and GIS), and ultra-hard (5–10 keV for SIS and GIS) images for each of the four ASCA detectors. We also created summed SIS0 + SIS1 and GIS2 + GIS3 images in all bands. These images will be used in the spatial analysis below. The SIS images were made with 6.3 pixel\(^{-1}\) resolution, and the GIS images were made with 15.0 pixel\(^{-1}\) resolution.

### 3.2. Spatial Analysis

We have used XIMAGE (Giommi, Angelini, & White 1997) and IDL to inspect the images created in § 3.1. At low energies, our results are consistent with those expected based on the ROSAT data. X-1 is observed to be the dominant X-ray source in NGC 1672 (see Fig. 4a), and we also detect X-3 and probably X-2 in the SIS images. We have compared the ASCA and ROSAT data to examine source variability. We do not find any strong evidence for variability, although source confusion (see § 3.1) significantly limits our variability analyses.

In the harder 2–10 keV and 5–10 keV images, however, NGC 1672 has a considerably different appearance (see Fig. 4b). The dominant 2–10 keV emission is observed to be coincident with the HRI sources X-3 and X-7 (in both the SIS0 + SIS1 and GIS2 + GIS3 images), and we detect only weak 2–10 keV emission from X-1. Note that X-3 was also found to be the hardest source in the ROSAT PSPC band by BH196. In the 5–10 keV GIS2 + GIS3 image, the only detectable emission from NGC 1672 is coincident with X-3 and X-7. NGC 1672 is not detected in the 5–10 keV band by the SIS detectors, probably because of their smaller effective areas in this energy range (see Tanaka et al. 1994).

### 3.3. Spectral Analysis

Because of the limited spatial resolution of ASCA (see § 3.1), we have been able to perform reliable spectral analyses for NGC 1672 as a whole only (see § 7.4 of Day 1998). At energies above \( \approx 3–5 \) keV, X-3 is the dominant source, but at lower energies our spectra contain contributions from X-1, X-2, and X-3. We have extracted spectra from each detector using all of the acceptable exposure time, and we have used only data for which NGC 1672 is reliably detected (0.6–5 keV for the SIS and 1–8 keV for the GIS). We have grouped our spectra so that there are 15 photons per spectral data point to allow the use of \( \chi^2 \) fitting techniques. We have first performed preliminary spectral fitting for each of the ASCA detectors separately, and although the errors were large we obtained consistent results. We have therefore jointly fitted the spectra from all four detectors, and we detail these results below. Aside from the absolute model normalizations, we tied together the fit...
Fig. 4.—(a) Iteratively smoothed *ASCA* GIS2 + GIS3 image in the soft 1.0–3.0 keV band. The sources detected by the *ROSAT* HRI are marked and labeled for comparison. Note that the dominant emission seen by *ASCA* is coincident with X-1. (b) Iteratively smoothed *ASCA* GIS2 + GIS3 image in the ultra-hard 5–10 keV band. Note that the dominant emission seen by *ASCA* is coincident with X-3 and X-7.

parameters across the four *ASCA* detectors. We use XSPEC (Arnaud 1996) for all spectral fitting below.

We start by fitting the data in the 2–8 keV band, where X-3 is the dominant source. We use a basic power-law model with the Galactic absorption column. This model provides an acceptable fit with $\chi^2 = 50.4$ for 56 degrees of freedom. We obtain a power-law photon index of $\Gamma = 1.62_{-0.40}^{+0.29}$ (fit parameter errors are for $\Delta \chi^2 = 2.71$), and there is no evidence for systematic positive residuals near the 6.4–6.97 keV iron Kα lines. The 2–8 keV flux is $4.5 \times 10^{-13}$ ergs cm$^{-2}$ s$^{-1}$, corresponding to a 2–8 keV luminosity for NGC 1672 of $1.4 \times 10^{40}$ ergs s$^{-1}$. We have then applied this same model to the full 0.6–8 keV band. We obtain a steeper power law with $\Gamma = 2.06_{-0.13}^{+0.13}$ and $\chi^2 = 167.4$ for 153 degrees of freedom. The fit is statistically acceptable, although we observe systematic positive residuals from 0.6–1.0 keV and systematic negative residuals from 1.1–1.6 keV. These are understandable in the context of the *ROSAT* spectral fitting presented in §2.3 of BH196; the emission from NGC 1672 below $\approx 2$ keV appears to be largely from hot, diffuse gas that is associated with X-1, X-2, and X-3 (i.e., it is not primarily the diffuse emission discussed in §2.3). If we take the best-fitting 2–8 keV model and extrapolate it downward in energy, we see clear positive residuals that are likely to be associated with the thermal gas emission (see Fig. 5). We note that such emission is commonly seen from galaxies with starburst activity (see, e.g., Ptak et al. 1999). We have added a Raymond-Smith component to our basic power-law model, and this provides a highly significant improvement in overall fit quality. We obtain a plasma temperature of $kT = 0.66_{-0.29}^{+0.16}$ keV, a photon index of $\Gamma = 1.65_{-0.23}^{+0.25}$, and $\chi^2 = 139.0$ for 151 degrees of freedom ($\Delta \chi^2 = 28.4$ compared with the basic power-law model; fit parameter errors are for $\Delta \chi^2 = 4.61$). The plasma temperature from our fit is consistent with that of BH196, and the underlying photon index agrees better with that seen in the 2–8 keV band. The derived plasma temperature is also in good agreement with the temperatures obtained for other starburst galaxies (see, e.g., Fig. 3 of Ptak et al. 1999). The plasma abundances are poorly constrained, and we have adopted solar abundances in the fit above. The derived plasma temperature, power-law photon index, and X-ray luminosity do not depend sensitively on the abundance assumptions for abundance enhancements up to a factor of $\approx 5$, and we note that Storchi-Bergmann, Wilson, & Baldwin (1996) argue for moderately supersolar abundances in the nucleus of NGC 1672. In reality, we believe that the thermal emission below $\approx 2$ keV is likely to arise from gas with a range of temperatures and abundances, and our single Raymond-Smith–component model should not be taken too literally (see Ptak et al. 1999 for further discussion on this matter). Comparison of the soft and hard X-ray luminosities of X-3

Fig. 5.—*ASCA* SIS (crosses with dots) and GIS (plain crosses) spectra of NGC 1672. A power-law model has been fitted to the data above 2 keV and then extrapolated downward in energy to show the deviations from a power law. Ordinates on the lower panel (labeled “$\chi^2$”) shows the fit residuals in terms of sigmas with error bars of size unity. Note the systematic positive residuals at low energies.
suggests that this source may suffer from significant intrinsic absorption (see § 4 for further discussion), and we have examined whether our data constrain an absorption column affecting only the power-law spectral component. Unfortunately, our data do not tightly constrain such absorption, and column densities ranging from 0 cm$^{-2}$ to $\approx 2 \times 10^{22}$ cm$^{-2}$ are allowed by our data. Because of significant ASCA-ROSAT cross-calibration uncertainties (see, e.g., Iwasawa, Fabian, & Nandra 1999) as well as the time variability of X-3, we have not performed detailed joint spectral fitting of the data from these two missions.

The $2-8$ keV flux we measure from NGC 1672 is $\approx 7$ times smaller than the $2-10$ keV flux of $3 \times 10^{12}$ ergs cm$^{-2}$ s$^{-1}$ given by Awaki & Koyama (1993), and our image analyses in § 3.2 show that most of the $2-10$ keV flux originates outside the nucleus. Thus, the ASCA data do not provide evidence for a highly absorbed nuclear X-ray source as might be expected for a Seyfert 2. However, the ASCA data do not rule out a Seyfert 2 nucleus in which the torus has a large enough column density to absorb almost all X-rays below 8 keV. Given the emission at other wave-lengths (see § 3.1 of BHI96), a nuclear X-ray source with luminosity up to $\approx 10^{43}$ ergs s$^{-1}$ appears plausible. We can estimate the required torus column density for a plausible scenario using our spectral fits above. We have added an extra $\Gamma = 2$ power law to our best 0.6–8 keV fit and assumed an unabsorbed $2-8$ keV flux of $3 \times 10^{12}$ ergs cm$^{-2}$ s$^{-1}$ for this power law (corresponding to a $2-8$ keV luminosity of $\approx 10^{43}$ ergs s$^{-1}$). To represent absorption by the torus, we added an extra absorption component acting only on this power law. To allow for consistency between data and model, the fit requires the extra absorption component to have a column density of $\approx 2 \times 10^{24}$ cm$^{-2}$. About half of the Seyfert 2 population have torus column densities as large as this (see, e.g., Risaliti, Maiolino, & Salvati 1999). Many Seyfert 2s with large torus column densities show strong iron Kα emission lines. While we do not see evidence for iron Kα lines in our data, our constraints are not tight. For a narrow iron Kα line at 6.4 keV, our 90% confidence upper limit on the equivalent width is 750 eV.

4. DISCUSSION, CONCLUSIONS, AND FUTURE OBSERVATIONS

We have presented new ROSAT HRI and ASCA data that constrain starburst and Seyfert activity in NGC 1672. Notably, we do not find any evidence for hard X-ray emission associated with the nuclear source X-1, despite the claims for Seyfert activity made on the basis of optical emission-line, infrared emission-line, X-ray, and radio data (see BHI96 for a review). We also find no evidence for long-term soft X-ray variability of X-1. If NGC 1672 indeed has a luminous Seyfert 2 nucleus, it must have been heavily obscured during the ASCA observation by a “Compton-thick” torus. Our X-ray spectral results stand in contrast to those of Awaki & Koyama (1993), who claimed to detect luminous power-law emission from an obscured Seyfert nucleus with $N_H < 3.2 \times 10^{22}$ cm$^{-2}$. While it is perhaps possible that the torus column density along our line of sight has increased by a factor of $\approx 60$ between the Ginga and ASCA observations, the simplest explanation for the discrepant results is that the Ginga data suffered from source confusion. The other arguments for Seyfert activity in NGC 1672, while entirely plausible, lack robustness. The reasoning based on the composite nature of the nuclear optical emission lines (Véron et al. 1981) relies on fairly subtle effects, and we note that Storchi-Bergmann et al. (1996) have recently found that the nuclear emission-line ratios can be explained via ionization by hot ($\approx 45,000$ K) stars. In this case, NGC 1672 may be an example of a nonactive galactic nucleus (non-AGN) LINER. Furthermore, Moorwood & Oliva (1988) failed to detect the broad Brγ line claimed by Kawara, Nishida, & Gregory (1987), and we are not aware of any confirmation of the radio variability suggested by Tovmassian (1968). While we must still admit the possibility of a luminous, highly obscured Seyfert nucleus in NGC 1672, the physical interpretation of its optical emission lines is not yet clear, and the balance of evidence appears to be shifting away from this.

The most interesting extranuclear source in NGC 1672 is X-3. We have demonstrated that X-3 shows large-amplitude soft X-ray variability on a timescale of $\approx 5$ yr, suggesting that it is a single object (or at most a few). X-3 has a peak observed soft X-ray luminosity of $\approx 2.5 \times 10^{39}$ ergs s$^{-1}$, and it probably has an even larger hard X-ray luminosity. If the hard X-ray emission of § 3.2 and Figure 4b originates from X-3 (the most probable possibility in our opinion), its 0.2–8 keV X-ray luminosity is $\approx 6 \times 10^{39}$ ergs s$^{-1}$. The fairly large ratio of hard to soft X-ray flux could be explained if X-3 suffers from some absorption within NGC 1672; the hard spectral components of starburst galaxies are often absorbed by column densities of $\approx 10^{22}$ cm$^{-2}$ (see, e.g., Ptak et al. 1999). The variability, luminosity, and extranuclear location of X-3 suggest that it is a powerful X-ray binary, young supernova remnant, or young hypernova remnant. No supernovae are listed for NGC 1672 in the Asagi Supernova Catalogue (Barbon et al. 1999). If X-3 is an accreting compact object that emits isotropically, the mass required by the Eddington limit is $\approx 45 M_\odot$. To our knowledge, the only source in our Galaxy with a comparable X-ray luminosity is GRS 1915+105 (see, e.g., Greiner, Morgan, & Remillard 1998), and X-3 ranks among the more luminous of the “super-Eddington sources” seen in nearby galaxies (see, e.g., Fabbiano 1998; Colbert & Mushotzky 1999; and references therein). The new X-ray sources we find in NGC 1672 (X-7, X-8, and X-9) are also quite luminous and exceed the Eddington limit for a 1.4 $M_\odot$ object. They too are probably X-ray binaries or supernova remnants, and sources with comparable luminosities are seen fairly frequently in nearby spiral galaxies (see, e.g., Read, Ponman, & Strickland 1997, hereafter RPS97).

We have compared the number and the luminosity distribution of our extranuclear X-ray sources with those of the nearby galaxies studied by RPS97, and NGC 1672 shows a moderately large although not extreme amount of extranuclear X-ray source activity. There are almost certainly many more X-ray binaries and supernova remnants lying below our current X-ray sensitivity threshold ($\approx 3 \times 10^{38}$ ergs s$^{-1}$).

A moderate-length Chandra observation holds particular promise for improving our understanding of NGC 1672. Separation of the diffuse nuclear X-ray emission from any pointlike central source would provide a sensitive probe for low-level Seyfert activity. In addition, Chandra would allow an excellent imaging study of the nuclear starburst X-rays
and, like the radio emission, the X-rays might trace the nuclear ring (see, e.g., Lindblad & Jörsäter 2000). Furthermore, Chandra would provide much better spectral constraints on X-3 and would detect X-ray binaries and supernova remnants down to \( \approx 5 \times 10^{37} \) ergs s\(^{-1}\) in this nearby starburst galaxy.

We thank M. Corcoran, H. Ebeling, E. Gotthelf, and an anonymous referee for helpful discussions, and we thank H. Ebeling for the use of his IDL software. We gratefully acknowledge financial support from NASA grants NAG5-4826 and NAG5-6023 (P. J. d N.), and NASA LTSA grant NAG5-8107 (W. N. B.).
