Abstract

Nickel catalysts supported on different carriers (θ-Al₂O₃, γ-Al₂O₃, HZSM-5 with γ-Al₂O₃, HZSM-5, and NaX) have been investigated for the partial oxidation of methane. All the supported nickel catalysts showed a high activity for the formation of synthesis gas, and γ-Al₂O₃ was the most effective among all the tested carriers. The effect of the heat-treatment temperature of the 3 wt.% Ni/γ-Al₂O₃ catalyst on its catalytic activity was studied, and a considerable decrease in its activity was observed by the heat-treatment of the catalyst at 1000 °C compared with the catalysts prepared by the 300–800 °C calcination. The XRD analysis suggested the formation of NiAl₂O₄ that is a non-reducible compound at the high calcination temperature. The addition of a modifier (Co, Ce, or La) to the 3 wt.% Ni/γ-Al₂O₃ catalyst increased the selectivity to H₂ and CO with the decreasing selectivity to CO₂, and the highest selectivity to H₂ was obtained by the 5 wt.% NiLa/γ-Al₂O₃. The developed 5 wt.% NiLa/γ-Al₂O₃ catalyst showed a high stability for 30 h for the partial oxidation of methane at 750 °C. The methane conversion reached 95%, selectivity to hydrogen 83% and 52% to carbon monoxide.

1. Introduction

According to the International Energy Agency (IEA), the demand of natural gas for energy production will increase until 2020. Methane is the main component of natural gas, and due to its economic feasibility, it has become the main source of synthesis gas and hydrogen produced by the reforming process [1].

The partial oxidation of methane into synthesis gas has created significant interest for researchers in the field of petrochemistry, because we will be able to use natural gas for at least 100–150 years as one of basic resources of the petrochemical industry [2–4]. Synthesis gas is also known to be an important material connecting methane with petrochemistry and can be directly converted to methanol which is a useful raw material for various chemicals; i.e., ethanol, formaldehyde, acetic acid, and methyl esters [5]. Additionally, the production of automobile fuel (MTG process) and alkenes (MTO process) from methanol have been actively investigated in order to achieve the practical use.

In the industrial production, although synthesis gas is produced by the steam-reforming of natural gas, the most promising one of all the known processes for synthesis–gas production is the oxidative conversion of methane. The composition of synthesis gas obtained in the process is more preferable for the production of methanol and liquid products by the Fischer-Tropsch reaction, because the cost of synthesis-gas produced by the partial oxidation of methane is estimated to be almost 1.5 times lower than that produced by steam reforming [6, 7]. In order to achieve a practical application of the oxidative conversion of methane, the development of highly active, stable, selective, and cost-effective catalysts are desired [8, 9].

The most effective and economic catalysts for the methane reforming are known to be the Ni-based catalysts, such as the Ni/γ-Al₂O₃ catalyst, due to its relatively low cost compared to other catalysts [10–12]. However, the main drawback of the Ni-based catalyst is the rapid deactivation of the catalyst caused by coke formation and/or sintering of the nickel under severe reaction conditions [13].
Various nickel-based catalysts, such as Ni-γ-Al₂O₃[14, 15], Ni-M-γ-Al₂O₃ (M = La [16], Co [17], Rh [18] and Cu [19]), and Ni supported on La₂O₃, CeLaO₃, and CeO₂ [20], were investigated for the oxidative conversion of methane. In these reactions, most of the catalysts showed a high activity, and the methane conversion value were in the range of 67–95%. However, the drawback of the catalyst is a low selectivity to the hydrogen formation.

It is well known that the introduction of cerium oxide to Ni-based catalysts as a promoter led to a significant improvement in their catalytic properties such as an increase in the activity and reduction of coke formation [21]. For example, the suppression of the coke formation can be achieved by the introduction of CeO₂, because having the high ability for oxygen storage allows regulating the oxygen concentration on the surface of the catalysis.

In this study, we investigated the performance of the nickel catalyst supported on various carriers, i.e., γ-Al₂O₃, θ-Al₂O₃, ZSM-5 with γ-Al₂O₃, ZSM-5, and NaX for the oxidative conversion of methane to synthesis gas. Moreover, the effects of promoting additives (CoO, CeO₂, La₂O₃) on the performance and the physicochemical characteristics of the nickel catalysts were also investigated.

2. Experimental

Experiments to test the efficiency of the catalysts were carried out using an automated flow catalytic device (FCI-1 LLC “Modern laboratory equipment” Novosibirsk, Russia). The device consists of three main parts: the preparation of the initial gas mixture, a quartz flow-type reactor, and a gas chromatograph for the product analysis. The reactor was a quartz tube of 25 cm in length, and its internal diameter was 9–9.5 mm. During the experiments, the reactor was vertically placed in an electric furnace, and the reactant mixture was supplied to the reactor from the top. After the reactant was passed through the catalyst bed, the converted gas left the reactor through a hole in the lower part of the reactor. The reaction was performed at atmospheric pressure and the temperature was studied in the range of 600–900 °C. The amounts of the reaction products were determined by an absolute calibration method using a gas chromatograph equipped with a thermal conductivity detector (GC-1000 LLC “Chromos” Russia). The separation of each component in a product was carried out by two columns of molecular sieves 13X and Porapak T, using argon as the carrier gas.

The catalysts were prepared by the impregnation of γ-Al₂O₃ (S_BET = 190 m²/g, 1.2 mm-φ; Shanghai Jiuzhou Chemicals Co., Ltd.) with a solution of Ni(NO₃)₂ · 6H₂O (Altei Company), drying at 350 °C (for 2 h), and then calcination at 500 °C for 3 h.

The physicochemical characteristics of the nickel catalysts were investigated by the following methods. The crystal phase and chemical composition of the catalysts were determined by X-ray diffraction analysis (XRD) using a D2 Phaser with a LYNXEYE high speed detector (Bruker AXS) and an X-ray fluorescent analysis using PW2400 (Spectris Co., Ltd.), respectively. The specific surface area, pore volume, and pore-size distribution were measured by low-temperature nitrogen adsorption at 77 K using BELSORP-mini II (BEL Japan, Inc.). Morphology of the catalysts was observed by a scanning electron microscope (SEM) using S-4100 (Hitachi High-Technologies Corporation) and a transmission electron microscope (TEM) using Technai G220 (FEI Company). The investigation of the surface composition and the electronic state of the nickel atoms were carried out by XPS (Shimadzu Corp., AXIS-Nova).

3. Results and Discussion

Carriers (θ-Al₂O₃, γ-Al₂O₃, HZSM-5 with Al₂O₃, HZSM-5, and NaX) with different properties have been investigated for the partial oxidation of methane. The evaluation of the catalytic activity was performed using a conventional flow reactor at GHSV = 4500 h⁻¹ and the ratio of the reactants was CH₄: O₂: Ar = 2:1:3.6 in the temperature range of 600–900 °C. Figure 1 represents the data obtained at the optimal reaction temperature being equal to 750 °C using only a support. The mixture of CO, CO₂, and H₂ was obtained during the reaction as products of the methane oxidation.

In this study, the partial oxidation of methane with oxygen was carried out with the reactants consisting of the stoichiometric oxygen/methane ratio for the formation of hydrogen and carbon monoxide:

\[
\text{CH}_4 + \frac{1}{2} \text{O}_2 = \text{CO} + 2\text{H}_2
\]

No significant effects of the specific surface area of the carrier on the catalytic activity were observed for the reaction. The highest activity was obtained by γ-Al₂O₃ with the specific surface area being equal to 170 m²/g, and the ratio of hydrogen to carbon monoxide was H₂/CO = 1.5. Although the NaX had the highest surface area (663 m²/g) among the tested carriers, its catalytic activity was lower than that of γ-Al₂O₃, due to the decomposition of the crystal structure during the reaction.
Nickel catalysts supported on the carriers were also tested for the partial oxidation of methane. The results are shown in Fig. 3. The conversion and the concentration of H\textsubscript{2} and CO increased by adding Ni on the carrier, and the ratios of H\textsubscript{2}/CO were close to the stoichiometric one based on the equation (1). The concentration of CO\textsubscript{2} was also reduced using supported Ni catalysts. The conversions of all catalysts except for Ni/NaX were not less than 90%, and the highest conversion of 95.3% was obtained using the Ni/γ-Al\textsubscript{2}O\textsubscript{3} catalyst, whereas the Ni/NaX catalyst showed the lowest conversion of 81.3%. The XRD patterns of all the tested catalysts are summarized in Fig. 2. After the reaction, the XRD pattern of Ni/NaX dramatically changed, because of the decomposition of the zeolite framework of NaX. In contrast, no significant changes were observed in XRD patterns of the other catalysts.

We investigated the influence of the content of nickel oxide on γ-Al\textsubscript{2}O\textsubscript{3} by changing the content from 0.05 to 10 wt.%. The data are shown in Fig. 4.

Figure 4 indicates that the increase in the nickel amount on γ-Al\textsubscript{2}O\textsubscript{3} improved the catalytic activity. The reaction using only γ-Al\textsubscript{2}O\textsubscript{3} afforded a 33.7% methane conversion. With the increasing nickel content from 0.05 to 5 wt.%, the methane conversion increased from 24 to 96%. When the reaction was performed using the catalysts having a Ni content over 3 wt.%, the methane conversion became 95–96%. Additionally, it is worth noting that the undesirable CO\textsubscript{2} significantly decreased from 27 to 5% when the amount of nickel increased from 0.05 to 7 wt.%.
Nickel Oxide Catalysts for Partial Oxidation of Methane to Synthesis Gas

Eurasian Chemico-Technological Journal 18 (2016) 25-30

Fig. 4 Results of methane oxidation using Ni/γ-Al₂O₃ catalysts having different nickel contents at 750 °C: 1 – 0.05%Ni; 2 – 0.5%Ni; 3 – 1%Ni; 4 – 3%Ni; 5 – 5%Ni; 6 – 7%Ni; 7 – 10%Ni / γ – Al₂O₃.

Fig. 5 XRD patterns of Ni/γ-Al₂O₃ catalysts calcined at 800 and 1000 °C.

The effects of the heat treatment temperature on the specific surface area, volume and size of the pores as well as the catalytic activity of the Ni/γ-Al₂O₃ catalyst were studied. The results are presented in Table 1. An increase of calcination temperature from 300 to 800 °C afforded a minor effect on the catalytic activity, whereas the increase in the temperature from 800 to 1000 °C caused a significant decrease in both the conversion (95 to 26%) and specific surface area (172 to 118 m²/g). The specific pore volume also decreased from 0.084 to 0.059 cm³/g, however, the average pore size only slightly changed. The observed effect is due to the formation of the spinel-like NiAl₂O₄, which is a thermodynamically favored compound at a higher temperature. The formation of NiAl₂O₄ prevented the reduction of NiO to Ni metal as the active species of the reforming. The XRD patterns of the Ni/γ-Al₂O₃ catalysts calcined at 800 and 1000 °C are shown in Fig. 5.

In the XRD pattern of the 800 °C – calcined Ni/γ-Al₂O₃ catalyst, diffraction peaks derived from Ni particles were clearly observed, whereas no significant peaks were detected in the pattern of the 1000 °C – calcined one. Based on the facts of the reforming and XRD analysis, we concluded that the low activity of the 1000 °C – calcined Ni/γ-Al₂O₃ catalyst is attributable to the formation of NiAl₂O₄ that is a non-reducible compound.

Figure 6 shows the TEM photographs of the Ni/γ-Al₂O₃ catalysts calcined at 800 and 1000 °C. The nickel particles having an approximate 10–20 nm diameter were clearly observed in the photograph (a). Meanwhile, we could not observe the nickel particles in the photograph (b) of the 1000 °C – calcined Ni/γ-Al₂O₃ catalyst.

The Ni/γ-Al₂O₃ catalyst was modified with oxides of cobalt, cerium, and lanthanum. The catalysts were evaluated during the reaction at the GHSV = 4500 h⁻¹ and the ratio of the reaction mixture was CH₄: O₂: Ar = 2:1:3.6. These results are shown in Fig. 7.

The modification of the Ni/γ-Al₂O₃ catalyst reduced the yield of CO₂ in the reaction products with the increasing CO yield. Among the tested catalysts, the NiLa/γ-Al₂O₃ catalyst was the most effective one for the formation of synthesis gas because of the decreasing CO₂ content from 11 to 0.3%. For the reaction using the La-modified catalyst, the H₂ yield also increased from 81% to 83%.

Fig. 6. TEM photographs of the Ni/γ-Al₂O₃ catalysts (after the reaction): (a) – 800 °C calcination and (b) – 1000 °C calcination.
| Catalyst   | T/°C | XCH₄/\% | XH₂/\% | XCO₂/\% | SCO/\% | Surface area/(m²/g) | Pore volume/(cm³/g) | Average pore size/nm |

Table 1

Effect of heat-treatment temperature on catalytic activity of Ni/γ-Al₂O₃

Fig. 7. Effects of second element addition to Ni/Al₂O₃ on activity and selectivity for partial oxidation of methane at 750 °C: 1 – Ni/Al₂O₃; 2 – NiCo/Al₂O₃; 3 – NiCe/Al₂O₃; 4 – NiLa/Al₂O₃.

Fig. 8. Long-term test of NiLa/γ-Al₂O₃ catalyst for partial oxidation of CH₄ at 750 °C.

The stability of the NiLa/Al₂O₃ catalyst was investigated for the partial oxidation of methane under the following conditions: T = 750 °C, GHSV = 1000 h⁻¹, t = 30 h, and CH₄/O₂ = 66.7:33.3. The results are presented in Fig. 8. As shown in the Fig. 8, the NiLa/γ-Al₂O₃ catalysts did not lose its activity for 30 h, and the H₂/CO ratio also showed a constant value being equal to 1.9 during the reaction. After 30 h, the selectivities of CO and H₂ increased to 98.8 and 97.3%, respectively, at the 88.3% methane conversion with the 1.2% CO₂ selectivity.

The SEM photographs of the Ni-M/γ-Al₂O₃ (M = La, Ce, and Co) catalysts used for 30 h indicated a different situation for the coke formation (Fig. 9). The Ni/γ-Al₂O₃ and NiCo/γ-Al₂O₃ catalysts formed a significant amount of the tube- or yarn-like cokes, whereas no significant amount of coke was observed on the surface of the NiCe and NiLa/γ-Al₂O₃ catalysts. These results suggested that the addition of La and Ce improved the surface properties of the Ni/γ-Al₂O₃ catalyst. We tried to determine the amount of coke on the Ni/γ-Al₂O₃ (after the reaction for 30 h at 750 °C) by TG-DTA measurement, however, no significant amount of coke was detected.

We attempted to clarify the properties of the nickel by XPS measurement, however, the 2p₂/₃ peaks derived from nickel were not detected for all the nickel catalysts after the reaction.

4. Conclusions

For the reaction of partial oxidation of methane using the Ni catalysts supported on various carriers, such as θ-Al₂O₃, γ-Al₂O₃, HZSM-5 with Al₂O₃, HZSM-5, and NaX, γ-Al₂O₃ was the most effective one among the studied carriers. The heat-treatment temperature of Ni/γ-Al₂O₃ affected the catalytic activity, and its calcination at 1000 °C caused catalyst deactivation by the formation of the non-reducible NiAl₂O₄.

The addition of modifiers (Co, Ce, and La) to the Ni/γ-Al₂O₃ catalyst increased the yields of H₂ and CO with the decreasing CO₂ content in the reaction products. We successfully developed the most effective NiLa/γ-Al₂O₃ catalyst, which showed a high stability for 30 h with excellent selectivities such as 83% to hydrogen and 52% to carbon monoxide at the 95% methane conversion.
