The microstructure of Sn-Ag-Cu (SAC) solder joints plays an important role in the reliability of electronics, and interlaced twinning has been linked with improved performance. Here, we study the three-dimensional (3-D) shape of interlaced regions in Sn-3.0Ag-0.5Cu (SAC305) solder balls by combining serial sectioning with electron backscatter diffraction. In solder balls without large Ag₃Sn plates, we show that the interlaced volume can be reasonably approximated as a hollow double cone with the common \( h_{100} \) twinning axis as the cone axis, and the \( h_{110} \) from all three twinned orientations making up the cone sides. This 3-D morphology can explain a range of partially interlaced morphologies in past work on 2-D cross-sections.

Key words: Lead-free solder, interlacing, microstructure, electron backscatter diffraction (EBSD), twinning

INTRODUCTION

\( \beta \)Sn is the main solid phase in most electronic solder joints,\(^1\) and dictates much of the electrical and mechanical properties of joints. The body-centered tetragonal (bct) structure is highly anisotropic. For example, the coefficient of thermal expansion\(^2,3\) and solute diffusivity\(^4\) vary between the \( a \)-direction and the \( c \)-direction of \( \beta \)Sn. In lead-free solder joints, \( \beta \)Sn usually presents only a few grain orientations, with single grain joints\(^5-7\) and three grain morphologies\(^1,5,8-11\) frequently reported in Sn-Ag-Cu (SAC) solders. The three orientations of \( \beta \)Sn are related via cyclic twinning around a common \( \langle 100 \rangle \) direction,\(^1,6\) and seem to come from a single nucleation event. These cyclic twin microstructures have been reported as either a beach-ball or interlacing morphology, or a mixture of the two.\(^9,12\) Electron backscatter diffraction (EBSD) techniques have been successfully used to identify crystal orientations and relationships between \( \beta \)Sn grains, such as the common twinning axis.\(^1,7,13,14\)

A SAC solder joint with an interlaced microstructure, composed of many small \( \beta \)Sn grains, shows increased mechanical properties, such as hardness and creep,\(^15\) as well as better reliability compared to a beach-ball microstructure, by delaying crack initiation.\(^16\) Furthermore, a solder joint of a single grain will have anisotropic mechanical properties, corresponding to \( \beta \)Sn anisotropy,\(^17\) and can result in early joint failure for certain grain orientations. The ability to control or predict interlacing in solder joints could therefore be beneficial in improving their reliability.

Lehman et al.\(^1\) proposed that the beach-ball morphology comes from \( \{101\} \) cyclic twinning, and that the interlaced morphology comes from \( \{301\} \) cyclic twinning. However, many SAC microstructures have an interlaced morphology near the apparent nucleation point and a beach ball morphology growing away from the interlaced region.\(^8,11\) Arfaei et al. proposed that the difference between the interlaced and beach-ball morphologies may be due to a change in preferred growth direction of \( \beta \)Sn dendrites, from \( \{110\} \).\(^8\) Their research into the interlaced nature of \( \beta \)Sn grains...
in SAC solder balls and joints concluded that increased $\beta$Sn nucleation undercooling (lower solidification temperature) favours larger areas of interlacing.

Past research of Sn-Ag-Cu solder balls contain micrographs of partially-interlaced regions with a range of morphologies. Examination of past papers revealed two frequently observed microstructures: a crescent shape and a ring of interlacing surrounded by a $\beta$Sn dendritic region, as listed in Table I. These two microstructures share the common feature of a band of $\beta$Sn interlacing between beach-ball-type cyclic twinned dendrites. While these two microstructural features are shown in various different papers, past work has not considered them in detail, and it is not clear if these shapes in two-dimensional (2-D) cross-sections belong to the same shape in three-dimensions (3-D). From micrographs in the literature, it also seems that these microstructures tend to form when there is a lack of primary IMC particles.

This study aims to build a deeper understanding of the formation of interlaced twinning in SAC solders by exploring the crescent and ring microstructures of $\beta$Sn interlacing in Sn-3.0Ag-0.5Cu (SAC305) solder balls. We focus on reconstructing the 3-D shape of interlaced regions by combining serial sectioning and EBSD.

**METHODS**

The majority of this study was performed on a SAC305 solder alloy made by mixing high-purity Sn, Ag and a Sn-10Cu master alloy and casting into an ingot. The composition of the alloy (wt%) was measured by XRF spectroscopy to be Sn-3.2Ag-0.47Cu, with main impurities of 0.018Sb, 0.006Pb and 0.002Ni, and Co, Fe, Zn and Bi, all $< 0.001$ wt%. To test for the generality of the findings, we also studied a small number of samples made from two further batches of SAC305: one from commercial ingot supplied by Nihon Superior, Osaka, Japan, and another made from commercial purity starting materials from our past work in Ref. 7.

The cast ingots were then cut into small pieces which were rolled into a foil of approximately 50 $\mu$m thickness. Small 1.5-mm-diameter disks were punched out of the foils and then melted in a ROL1 (IPC J-STD-004) (Nihon Superior) flux on a hotplate at 240°C. The disks melted and formed spheres of approximately 500 $\mu$m diameter under surface tension. The solder balls were then cleaned in an ultrasonic bath, with ethanol as a cleaning solvent.

Solder balls were then placed in an aluminium pan and run in a Mettler Toledo differential scanning calorimeter to melt and solidify them, and to measure the solidification temperature. All the samples, unless stated, were heated up to a peak of 240°C and cooled with a cooling rate of $-20$ K min$^{-1}$ (−0.333 K s$^{-1}$) under a N$_2$ gas atmosphere. Some samples were cycled only once, and others were cycled multiple times, up to 12 times. One sample was heated to a peak temperature of 300°C.

The samples were mounted in VersoCit cold-setting acrylic resin (Struers), ground on SiC grinding paper with water as lubricant, up to #4000 grit, and polished with colloidal silica (OP-S; Struers). Micrographs of the samples were then taken under reflected light and polarised light microscopy. Some of the samples were ground and polished a few times, as normal, but not up to the apparent mid-section of the sample. They were then cut out of the resin and remounted at approximately right angles, and ground again, with multiple cross-section micrographs being taken throughout the rest of the sample. This is illustrated in Fig. 1.

Reconstruction of the sample volume was carried out in Inkscape image vector graphics software (Inkscape v.0.91). Figure 2 shows the method followed from Ref. 21 in creating the front projection and the top projection to create an isometric volume reconstruction of solder balls. The front projection was taken as the first two sections of the sample, and the top projection was taken as the cross-sectioning after sample remounting. Aligning the samples in 3-D was approximated by lining up the chord length of the sections with the cross-section outline. This means that the presented volume reconstructions are not dimensionally exact, but serve well as an approximate representation of the sample volume. The micrographs were cropped and

Table 1. Observed crescent and ring morphologies of $\beta$Sn interlacing in the literature; this is not an exhaustive list of literature.
Samples were also analysed using EBSD (Bruker eFlash HR detector) in a scanning electron microscope (Zeiss Sigma FEG-SEM) to reveal crystal orientations in the samples. EBSD results were analysed in Bruker Esprit 2.1 software.

RESULTS AND DISCUSSION

Figure 3 shows the results of serial-sectioning, EBSD and reconstruction of a SAC305 solder ball with a melt undercooling of 47 K. Figure 3a–f illustrates how the interlacing shape changes through the volume of the sample and presents a crescent-shaped region of interlacing in Fig. 3b, d and e. Figure 3i shows the crescent interlacing region measured by EBSD, and the corresponding pole figure in Fig. 3j shows that the sample is made up of 3 βSn grain orientations, with a common {100}, whose normal direction is the twinning axis. From the 3-D reconstruction in Fig. 3m, we see that the interlaced area (red) starts as a circle in the lower right of the sample, then opens up into a ring and crescent shape towards the top right. Note that the front reconstruction of the microstructure has been flipped to open the 3-D structure, such that the microstructure observed in the microscope is reconstructed in the direction out of the page from left to right. EBSD results from all three cross-sections in Fig. 3g–l show that only three βSn grain orientations were detected in this sample.

Figure 4 shows another example from a sample with a melt undercooking of 53 K. The interlaced area has crescent, circular and ring-like shapes between sections. Again, from the reconstruction in Fig. 4m, the interlaced region can be seen to open up from the top right towards the bottom left, starting circular with a core-like feature in the centre, and creating a successively larger ring-like morphology. The crescent shape is observed as a perpendicular cross-section of the circular shape. The EBSD results shown in Fig. 4g–l show that the sample only contains three βSn grain orientations that are cyclic twinned, and we can clearly deduce that the perpendicular EBSD results show consistent grain orientations in the pole figures.

Microstructures in the two reconstructed samples are shown in more detail in Fig. 5. From the optical micrographs in Fig. 5b and f, we see that the eutectic IMCs become finer towards the centre of the interlacing region. Likewise, the interlacing grain size decreases towards the centre of the region. This is consistent with past observations of these structures.\textsuperscript{18} From the polarised micrographs Fig. 5c and g, we see that the centre of these interlaced areas are actually made up of a few larger βSn grains which appear as a core surrounded by the interlacing region. This is confirmed by EBSD in Fig. 5d, with blue and purple grains substantially larger than the surrounding interlaced area. In further cross-sections, these cores increase in size and become dendritic βSn regions inside the widening interlacing ring/crescent (Figs. 3, 4). This differs from the core structures reported by Mueller et al.,\textsuperscript{18} which have a uniform circular cross-section and elongated ellipsoid shape.

From Figs. 3m and 4m, the 3-D shape of the envelope bounding the interlaced region can be deduced to be a hollow double cone. This proposed structure is explained in Fig. 6, with Fig. 6d showing the overall shape of this hollow double cone. Figure 6a shows how such a cone can be constructed with the [100] direction of βSn running along the cone axis, and the two \(\{110\}\) directions inclined at 45° to the axis. Figure 6b shows how the commonly contrast-corrected using ImageJ software (ImageJ 1.51h).\textsuperscript{22}
observed ~ 60° cyclic twinning around the shared [100] direction produces six (110) directions revolved around the cone axis forming the cone sides. Powell et al. have shown that βSn growth often deviates from (110), with a c-component to growth, i.e. (11w) with 0 < w ≤ 1. In this case, there
are twice as many twinned growth directions as for (110), and these are closer to a continuous cone, as shown on the pole figure in Fig. 6c using (221) as an example. For the case of (111) growth, note that two adjacent βSn cyclic twins (i.e. [111] blue and [111] red in Fig. 6c) nearly coincide, with a misorientation of around 1° if we treat the cyclic twin as three 60° rotations. Thus, we see that cyclic twinning with a shared [001] direction and growth along (110), or (11w) with 0 < w ≤ 1, produces an envelope shape similar to a double cone with the nucleation point at the centre.

Considering the pole figures in Fig. 3m and Fig. 4m (note that for the left-hand pole figure the z-axis points into the page towards the left, and for the right-hand pole figure the z-axis points upwards), we see that the cone structure has the (110) cyclic direction forming a ring in the direction of the cone opening (in bct such as βSn, {110} normals and (110) directions are coincident vectors). Additionally, the [100] twinning direction is exactly in the centre of the (110) ring, and corresponds well with the cone axis.

Figure 7 shows how this interlaced cone can be intersected (such as when grinding a sample) to form crescent-shaped and ring-shaped conic sections, alongside examples of real observed microstructures which match this conic section. Figure 7a shows a section forming a crescent-shaped interlaced area as exemplified in Fig. 7b–e. A conic section forming a ring Fig. 7f can be observed in Fig. 7g–j. In Fig. 7d and i, a primary IMC is visible in the cross-section, which is shown enlarged in the inset. In Fig. 7d, a primary Ag₃Sn plate is visible in the optical micrograph, on the left side of the sample near the edge of the crescent-shaped interlacing, whereas in Fig. 7i, a primary Cu₆Sn₅ rod cross-
section is observed inside the crescent/semi-ring of interlacing. The cross-sections in Fig. 7e and j come from a single sample containing the cone morphology at different grinding depths, and show that this interlacing structure is also found after cooling from different peak temperatures.

EBSD of sections from multiple different balls provides further support for this 3-D structure. The results of some of these conic sections are shown in Fig. 8. From the [110] pole figures and the proposed conic section, we see how the cyclic twinned (110) directions form the cone walls, and that the (100) twinning axis (shown as a blue triangle on the [110] pole figures) points in the direction of the cone axis. In Fig. 8a, for example, we see that the V-shape of the interlaced region, with the centre of the cone near the sample surface, has the cone axis running left-to-right, whereas in Fig. 8b, the V-shaped interlaced region has its cone axis running up-and-down. Looking back at the reconstructions in Figs. 3m and 4m, we see that the cone centre, or tip, seems to be near the sample surface, suggesting that this is the likely nucleation point of the cone structure. If the cone structure nucleates near the sample surface, as implied by the observed microstructures, with a random orientation, the possible growth directions are limited by the sample shape and the availability of liquid around the nucleation point. It is then probable that half of the cone structure will grow in the direction of the sample edge and terminate. The proposed nucleation and growth leads to structures observed in Fig. 8a and b, whereas if nucleation of this cone structure occurs in the bulk of the sample a full X-shaped morphology will be observed in some cross-sections. Note that, in Fig. 8a and b, while there are similarities in their V-shaped area of interlacing, Fig. 8a has a near-horizontal (100) twinning axis whereas Fig. 8b has a near-vertical (100) twinning axis, which leads to the different shaded regions on the double cone in the final column. Figure 8c–e show how the cone structure cross-sectioned nearly perpendicularly to the cone axis results in circular, ring and crescent-shaped interlaced regions, like those reported in the literature.1,9,18–20

Figure 9 shows how the βSn growth directions of two samples form the conical shape around the common (100) direction. Figure 9c and f shows the 6 (110) and the 12 (221) directions forming a ring around the twinning axis/cone axis (blue triangle). Any growth direction of (11w) type, (with w between 0 and 1) will also lie on that ring, as shown in Fig. 6c, forming the sides of this hollow double cone. Figure 10 shows the thickness of the interlacing regions for the samples presented in Fig. 8. The thickness of the interlacing region is seen to vary greatly in Fig. 10a, from 73 μm to 172 μm, depending on the position of the measurement. A similar variation of thickness is observed in the other samples in Fig. 10b–e, with all the samples showing...
a general range of thickness of between 70 \( \mu \text{m} \) and 120 \( \mu \text{m} \). Additionally, the cross-sections in Fig. 10a and b do not show a relationship between the thickness and the distance from the cone origin, so it is impossible to correlate the distance from origin of the samples in Fig. 10c–e where the cone axis is out of plane. Clearly, Fig. 10d is closer to the origin of the cone than Fig. 10c or e, yet the cone widths are about the same. There is some indication in the literature that thinner ring/crescent shapes (12–60 \( \mu \text{m} \), Sn-3Ag-0.7Cu 270 \( \mu \text{m} \) solder ball, and 30 \( \mu \text{m} \) Sn-4Ag-0.9Cu 270 \( \mu \text{m} \) solder ball),\(^{19}\) indicating that ball size and composition may play a role which should be investigated further.

A further feature in this work was that samples that contained interlaced morphologies consistent with a hollow double cone (e.g. Figs. 3–8) rarely contained any observable primary Ag\(_3\)Sn plates or primary Cu\(_6\)Sn\(_5\) rods. The smallest primary Ag\(_3\)Sn detected in this study was 20 \( \mu \text{m} \) long, and between 0.8 \( \mu \text{m} \) and 2 \( \mu \text{m} \) thick, and smaller particles are likely to be missed in a 2-D cross section. While it is possible that larger primary IMCs were missed in samples in which only a single cross-section was studied, we note that, in Figs. 3 and 4, out of the six serial cross-sections covering most of each sample, none contained any observable primary IMCs, even though the melt undercooling reached 53 K, which is well below the Ag\(_3\)Sn and Cu\(_6\)Sn\(_5\) metastable liquidus surfaces.\(^{24}\) Figure 7d and i shows cross-sections of interlacing morphology, consistent with a hollow double-cone model, which do contain primary IMC particles. We present these examples to
highlight that primary IMCs can be present with double-cone interlacing (i.e. the absence of primary IMCs is not a prerequisite for the hollow double-cone shape of interlacing). However, in these samples, the primary IMCs seem to be away from the likely nucleation point of the cone and are not thought to strongly influence its formation.

Additionally, from the EBSD results in Figs. 3, 4 and 8, we see that the β-Sn grain structure is consistent with a simple cyclic twinning around a common (100) plane direction of just three β-Sn grains. Even in the multiple cross-sections in Figs. 3 and 4, only three β-Sn grain orientations are observed. This result is consistent with past studies, and more complex interrelated cyclic twinning, previously reported by Ma et al., was not observed here in hollow double-cone morphologies. This is most likely due to the nucleation of δ-Sn in the solder balls before that of Ag₃Sn, as opposed to the droplet nucleation study of Ma et al., where a large Ag₃Sn particle was always present as a substrate for the δ-Sn.

The hollow double-cone structure identified here seems to be consistent with the cyclic twinned-nucleus model by Lehman et al.¹ For both their (101) and (301) twinned-nucleus models, extending the (110) growth directions from such a nucleus does indeed form cone sides, as was illustrated in the pole figure in Fig. 6c. However, since Fig. 6 and the twinned-nucleus models of Lehman et al.¹ all plot directions from the same type of cyclic twin, they must be geometrically consistent in this way. It is therefore difficult to confirm or rule out either twinned-nucleus model as the origin of a hollow double-cone structure.

Interlaced regions whose envelope shape is a hollow double cone seem to be common in SAC305 solder balls with a nucleation undercooling between 25 K and 60 K, that are partially interlaced, and contain little or no primary IMC. From the SAC305 samples studied here, 78 of them had a partially interlaced microstructure and no primary Ag₃Sn observed in the cross-section, and out of those, 11 samples could be fully confirmed to contain a hollow double-cone interlacing. Many other SAC305 samples showed 2-D microstructures consistent with a hollow double cone, but these could not be confirmed without further in-depth analysis, since this structure can only be fully confirmed in samples that were serially-sectioned with a 90° rotation combined with EBSD (e.g. Figs. 3, 4), or in certain fortuitously cross-sectioned samples (e.g. Fig. 8).

The presently identified hollow double-cone shape is consistent with the frequently reported crescent and ring interlaced morphologies in 2-D sections of SAC solder balls, and also the V-shaped envelope identified in this work. We note that other interlaced morphologies are also present in micrographs in the literature, especially in samples with a higher fraction of primary Ag₃Sn and Cu₅Sn₅ crystals, which are not consistent with a hollow double-cone model. Other interlaced morphologies, including those formed in the presence of primary Ag₃Sn, will be presented and discussed in a separate manuscript. Further work is required to deduce the 3-D shape of the envelope bounding the interlaced regions in these cases.

CONCLUSIONS

This study carried out an in-depth analysis of the shape of β-Sn interlaced regions in ~ 500-μm-diameter freestanding Sn-3Ag-0.5Cu solder balls. After performing serial sectioning combined with EBSD to reconstruct the 3-D volume of the interlaced regions in selected samples, and comparing with cross-sections from multiple samples, the following conclusions can be drawn:

1. Some samples have been found to contain a hollow double cone of interlacing, with the [100] twinning axis being the cone axis, and the 6 cyclic twinned (110) growth directions, or 12 (110) growth directions, forming the cone sides.
2. The circular, ring, and crescent-shaped interlaced features reported on 2-D sections in the literature all belong to this one interlaced shape in 3-D. Additionally, a V-shaped interlaced structure was measured in this work that also belongs to the same hollow double cone structure.
3. The tip/centre of the cone is likely to be the nucleation point of β-Sn, and was commonly found near (and possibly at) the sample surface.
4. These cone structures were found in samples with no, or only a small amount of, primary Ag₃Sn plates or Cu₅Sn₅ rods.
