1. Introduction

Large disturbances in power systems are difficult to precisely model and may require imposing unrealistic assumptions when modeling them. Their significant inherent uncertainty mainly causes the difficulty. This study investigates a nonlinear model of Single Machine Infinite Bus System (SMIBS), and we design an advanced robust control law that guarantees asymptotic stability under such exacting conditions. In this work, we propose an Adaptive Sliding Mode Control (ASMC) design implemented on a fifth-order nonlinear SMIBS to handle those uncertainties without prior knowledge about its upper bounds. We develop the ASMC with gains of two nested adaptive layers to asymptotically stabilize the system's internal states, the machine's terminal voltage, and power angle within a region of unknown bounded uncertainties while mitigating the chattering phenomena associated with conventional Sliding Mode Control (SMC). To verify the design's effectiveness and prove the conducted Lyapunov theoretical stability analysis, we simulate the occurrence of a large disturbance represented by a 3-phase fault at the system's universal bus. The results show that the ASMC can successfully achieve asymptotic stable output errors and stabilizing the SMIBS internal states after the clearance of the fault. Moreover, the ASMC noticeably outperforms the SMC in chattering mitigation, where the ASMC's signal is significantly smoother than that of the SMC.
dq0 frame. The objective of the work presented by Fatima in [2] is to develop an adaptive controller for a synchronous generator driven by a hydraulic turbine connected to an infinite bus. Therefore, the model accounts for the drive-side dynamics, and hence two additional states are considered, water flow and valve opening, making the model with ninth order. Šundrica's aim in [3] is to introduce a control system the achieves high-performance speed tracking of a synchronous motor. Consequently, the SM dynamics is formulated with a seventh-order model considering the states as stator currents, rotor flux linkages, rotor angular speed, and load torque. Gao in [4], on the other hand, is aiming to investigate the transient behavior of synchronous motor's speed during start-up, and accordingly, a sixth-order model is considered with presenting the states as the flux linkages in the DQ frame, field voltage, and rotor angular speed. Since Sadabadi’s purpose in [5] is only performing system identification of the SM, the considered model in the study is like the one discussed by Kundur in [1].

Generally speaking, the ultimate purpose of establishing nonlinear models of SM when acting as generators is studying their stability under large power system disturbances during faults or sudden significant change in the load; these are both considered as significantly unpredictable uncertainties within the system [15]. In that sense, the "strength" of a generator-dynamic performance is methodically investigated to ensure satisfactory performance under such uncertain exacting situations. Under these situations, the strength principally means how strong the generator in terms of supporting the system voltage while at the same time reducing the oscillations and settling time of the power angle and frequency [9]. Although that stability analysis of synchronous generators was historically assessed deeply for traditional systems, the sharp incline in Distributed Generation (DG) penetration recently has brought attention to researchers for investigating their impacts on generators stability, the works presented in [10]-[13] are few of them among others. Besides the fact that this penetration induces further uncertainties into the system, DG penetration (for example, Renewable Energy Sources) affects the stability of traditional systems by reducing the overall inertia and limiting the capabilities of supplying short circuit current [14]. All of these consequences directly impact synchronous generators' dynamic performance during large disturbances. Therefore, the challenges above motivated researchers to develop more advanced controllers to enhance the SM dynamic performance. For instance, Prachitara in [11] proposed a sophisticated methodology to estimate the controller gains parameters of a system composed of Photovoltaic (PV) and diesel generators. The presented harmony search-based hybrid firefly algorithm (IHFA) in the paper works by estimating the gain parameters such that the damping of the overall system is optimized, and in turn, the stability is improved. Interestingly, as presented in [12] by Siming, the stability of a windfarm power plant is enhanced by integrating synchronous motor-generator pair with it and controlling the active power of the pair with a closed-loop controller; this consequently improved the system inertia and restrained the oscillation of power angle and frequency. To this end, we believe that SMC, as a candidate control law for SMIBS, worth investigating and may open the door for further research in hybrid power systems that constitute conventional and renewable power sources.

We need to point out here that the literature related to Sliding Mode Control (SMC) designs for SMIBS are limited. Chang [20] proposed a nonlinear SMC for a synchronous generator system to stabilize the rotor angle and terminal voltage under known disturbances. On the other hand, a third-order linearized model of a SMIBS with SMC is discussed by Awelewa in [21]. Awelewa ’s objective is to design a control law for the excitation system that ensures sufficient robustness under the system’s parameters variation. The severe disturbances in power systems, such as faults, are practically unpredictable. This unpredictability is caused by many factors such as fault location, connected load, and running generators. Moreover, controllers based on linearized models can only perform well around the vicinity of an equilibrium point; hence they most probably would fail when exposed to large external disturbances. Thus, designing SMC for synchronous generator infinite bus system while assuming known uncertainties or considering a linearized model to achieve asymptotic stability under large
It is noteworthy that SMC has been through significant advancement recently. One well-known controller is the Higher Order-Sliding Mode Control (HOSMC) introduced by the Levant in [16]. The HSMC strength lay in the fact that it can altogether remove chattering effects if appropriately designed [16]. However, it has a significant drawback: it needs the bounds of the system uncertainty to be priorly known. Although that super-twisting SMC circumvents this drawback, its implementation requires the knowledge of the bound of the uncertainty derivative [25]. One approach to handle these difficulties in the design of HOSMC and super-twisting controllers is the implementation of observer-based algorithms, see for example [22], [23] and [24]. The other approach introduces adaptability into the control algorithm, hence designing an ASMC that can adaptively estimate the uncertainty bounds. For example, the ASMC law developed by Abadi et al. in [26], namely Adaptive Non-singular Terminal SMC (ANTSMC), is implemented for synchronizing smart grid chaotic systems with the requirement of continuously estimating the bounds of the uncertainties presented in the system. It is also the case in the proposed algorithm of Alinaghi in [27]. Edwards et al. presented a novel ASMC algorithm in [18] when he proposed a nested two-layer adaptive scheme that neither requires the estimate of the uncertainty upper bound nor the bound of its derivative. We believe that the Edwards framework is remarkable because it significantly reduces the control algorithm complexity and enhances its robustness.

The novelty of this work is in the design of an advanced controller for a SMIBS. Our contribution, in particular, is fourfold as described below:

- We are designing a nested two-layer ASMC for a fifth-order nonlinear SMIBS Multi-Input-Multi-output (MIMO) model that guarantees asymptotic stable outputs' errors and system's internal states within finite time under unknown bounded uncertainties.
- The design procedure guarantees to offset bounded unknown uncertainties with significant mitigation of chattering effect, which is usually associated with conventional SMC.
- Our design approach neither requires a priori knowledge about the uncertainties' upper bound nor the bound of its derivative. Therefore, the stage of estimating uncertainties in our control algorithm is completely abolished.
- The complete system's nonlinearity is modeled as unknown uncertainties; this besides any large external disturbance. This helps in absorbing any unmodeled system or disturbance dynamics. Also, following this approach, the complexity of the control design is significantly reduced since the terminal voltage, one of the system outputs, is highly nonlinear.

This manuscript has the following structure. In section 2, the fifth-order nonlinear model of the SMIBS is developed. We then proceed to the design of the closed-loop system utilizing Adaptive Sliding Mode Controller in 3. A comprehensive simulation that assesses the overall performance of the designed closed-loop system is presented in 4, and the manuscript is finally concluded in section 5.

2. Multi-Input-Multi-Output Synchronous Machine Infinite Bus State-Space Model

As stated earlier, the model selection is usually based on the objective of the study. This work aims to develop a control law that asymptotically stabilizes the terminal voltage and power angle of an SM connected to an infinite bus using field voltage and mechanical torque as control variables. Hence, the selected model is quite similar to the nonlinear electro-mechanical seventh-order presented by Fodor in [6], with, however, minor modifications derived from [7]. Note that all variables and parameters mentioned henceforth are defined in Table 1 and Table 2, respectively. The overall power system that is under investigation is shown in Fig. 1.

| $D$       | Damping constant                                 | 2.004           |

*Representing the equivalent impedance from the generator terminal to the infinite bus

Considering $v_f$ and $T_{mech}$ as the model inputs, the overall state-space model is described as follows:

$$\dot{x} = F(x) + Bu, \quad y = [v_t(x) \quad x_4]^T$$

Where

$$x = [i_d \quad i_q \quad i_F \quad \theta \quad \omega]^T = [x_1 \quad x_2 \quad x_3 \quad x_4 \quad x_5]^T$$

$$F(x) =
\begin{bmatrix}
A_{11}x_1 + A_{12}x_3 + A_{13}x_2x_5 + A_{14}\sin(x_4 - \theta) \\
A_{21}x_1x_5 + A_{22}x_3x_5 + A_{23}x_2 + A_{24}\cos(x_4 - \theta) \\
A_{31}x_1 + A_{32}x_3 + A_{33}x_2x_5 + A_{34}\sin(x_4 - \theta) \\
(x_5 - 1)\omega_r \\
A_{51}x_1x_2 + A_{52}x_2x_3 + A_{53}x_5
\end{bmatrix}$$

Magdi S Mahmoud (An Adaptive Sliding Mode Control for Single Machine Infinite Bus System under Unknown Uncertainties)
\[ B = \begin{bmatrix} B_{11} & 0 & B_{31} & 0 & 0 \\ 0 & 0 & 0 & 0 & B_{52} \end{bmatrix}^T; \]

\[ u = [v_f \ T_{\text{mech}}]^T \]

with \( A_{ij} \) and \( B_{ij} \) elements in (1) are properly defined by Akhrif in [7]. The values of these elements depend on the machine design parameters are defined in Table 2.

Remarks

1. The model is MIMO, and the input dynamics, \( v_f \) and \( T_{\text{mech}} \), are neglected.
2. The phase voltages are assumed to be balanced at all times (even during faults), and hence the 0 component in the \( dq\theta \) frame can be neglected.
3. The model is highly coupled, and the nonlinearity is observed in all states' dynamics except for the power angle \( \theta \).
4. Model bifurcation analysis is worthy since common practical machine defects during its operation will alter the parameters. For example, such a common defect could be stator windings turn-to-turn insulation failure, shorted turns in the field windings, or combined. However, this type of analysis is out of the scope of this work.

The nonlinearity in \( F(x) \), in (1), can be seen as a separated perturbation term from a linear term, and hence linearization techniques can be implied to investigate the stability of the equilibrium points. The open-loop perturbed system can be depicted as linear and nonlinear segregated terms [8]:

\[ \dot{x} = F(x) = Ax + g(x) \tag{2} \]

Where:

\[
A = \begin{bmatrix} A_{11} & 0 & A_{12} & 0 & 0 \\ 0 & A_{23} & 0 & 0 & 0 \\ A_{31} & 0 & A_{32} & 0 & 0 \\ 0 & 0 & 0 & 0 & \omega_r \\ 0 & 0 & 0 & 0 & A_{53} \end{bmatrix} \quad \text{and} \quad g(x) = \begin{bmatrix} A_{13}x_2x_5 + A_{14}\sin(x_4 - \theta) \\ A_{21}x_1x_5 + A_{22}x_3x_5 + A_{24}\cos(x_4 - \theta) \\ A_{33}x_2x_5 + A_{34}\sin(x_4 - \theta) \\ 0 \\ A_{51}x_1x_5 + A_{52}x_2x_3 \end{bmatrix}
\]

Without loss of generality, and for notation brevity\(^1\), it is assumed that \( x = 0 \) is an equilibrium point such that \( F(0) = 0 \) (2). It can be observed that \( g(x) \to 0 \) as \( x \to 0 \); hence, the nonlinearity in (2) is vanishing around the vicinity of the equilibrium points. Thus, linearization techniques can be applied to investigate the stability of those equilibrium points.

3. Adaptive Sliding Mode Control Design

As mentioned before, the design of the controllers is quite challenging as its main objective is to asymptotically stabilize the output errors and stabilizing the system's internal states under unknown uncertainties. To achieve this objective, an ASMC is selected. In the ASMC scheme, with properly structured sliding surfaces and Lyapunov function, an asymptotic stable closed-loop system can be guaranteed, as shown in the upcoming sections. The design of the controllers will take several steps. First, two sliding manifolds will be designed, each of which handles a sub-system, i.e., the electrical and the mechanical sub-systems. After that, the reachability conditions are deliberated in detail to select the controllers' gains accordingly. Like Edwards et al. method [18], the adaptation rules of these gains are then derived so that

\[ x = x - \dot{x} = \dot{x} = F(x) = F(x + \dot{x}) \iff \xi(x), \xi(0) = 0, \text{ but here the notation is not changed to ease the process of following the analysis.}\]

---

\(^1\) z = x - \xi \rightarrow \dot{z} = \dot{x} = F(x) = F(x + \dot{x}) \iff \xi(x), \xi(0) = 0, \text{ but here the notation is not changed to ease the process of following the analysis.}\n
Magdi S Mahmoud (An Adaptive Sliding Mode Control for Single Machine Infinite Bus System under Unknown Uncertainties)
the chattering effects resulting from the switching functions are minimized. Finally, the asymptotic stability of the overall system is investigated through the Lyapunov stability approach. The overall closed-loop system with the ASMC controllers’ designs is shown in Fig. 2 (sliding manifolds coefficients are not included in the Figure for simplicity).

**Fig. 2.** SMIBS overall closed-loop system block diagram

### 3.1. Design of Sliding Manifolds

Since the objective of ASMC is to stabilize outputs’ errors as well the internal system states, then the two sliding surfaces are selected as follows:

\[ S_1 = \lambda_1 e_{y_1} + \lambda_2 \int e_{y_1} + \lambda_3 (x_3 - x_1) \]  
(3)

\[ S_2 = e_{y_2} + \dot{e}_{y_2} \]  
(4)

Where \( e_{y_1} = y_1 - y_{1\text{ref}}; \) \( e_{y_2} = y_2 - y_{2\text{ref}} \) are the output errors, \( y_{1\text{ref}}; y_{2\text{ref}} \) are constant references and \( \lambda_1, \lambda_2, \lambda_3 \) are the sliding manifolds coefficients. Noteworthy, the structure of the sliding surfaces in (3) and (4) are specifically selected so that during maintaining sliding, that is when \( S_1 = S_2 = \dot{S}_1 = \dot{S}_2 = 0 \), the output errors are zeros while all states in \( x \) will have finite values as \( t \to \infty \); this is proven below.

First, let us consider the first sliding manifold in (3). While sliding \( S_1 = 0 \), if the manifold’s coefficients are selected such that \( \lambda_2 < 0 < \lambda_1 < \lambda_3 \), then:

\[ \lim_{t \to 0} \lambda_3 (x_3 - x_1) = \Delta x_3 \]

Where \( \Delta x_3 \) is a finite constant represents the difference between \( x_3 \) and \( x_1 \) at steady-state. Consequently, as \( t \to \infty \):

\[ \lambda_2 \int e_{y_1} = -\lambda_3 (x_3 - x_1) \to \lambda_1 e_{y_1} = 0 \]

Hence, at sliding \( S_1 = 0 \), the first output error \( e_{y_1} \) is zero while the states \( x_1, x_3 \) and \( x_2 \) are all with finite values.
For the second sliding surface in (4), during sliding $S_2 = 0$, the two terms must equal to zero:

$$e_{y_2} = \dot{e}_{y_2} = 0$$

Since $y_2 = x_4$, this implies:

$$e_{y_2} = y_2 - y^{ref} = x_4 - y^{ref} = 0 \rightarrow x_4 = y_2 = y^{ref}$$  \hspace{1cm} (5)

From the dynamics of $x_4$ in $F(x)$ in (1) and the fact that of $\dot{e}_{y_2} = 0$ when $S_2 = 0$:

$$\dot{e}_{y_2} = \dot{x}_4 = (x_5 - 1)\omega_r = 0$$

As $t \rightarrow \infty$:

$$\dot{x}_4 = (x_5 - 1)\omega_r = 0 \rightarrow x_5 = 1$$

Hence the second output error $e_{y_2}$ is zero while $x_4$ and $x_5$ both have finite values as $t \rightarrow \infty$ when $S_2 = 0$.

### 3.2. Reachability Conditions

To guarantee reachability of errors and states trajectories into the surfaces $S_1 = S_2 = 0$, both conditions $S_1 \dot{S}_1 < 0$ and $S_2 \dot{S}_2 < 0$ shall be achieved. The achievability of reaching these manifolds is proven separately in the following subsections.

1) **Reachability Condition of First Sliding Manifold**

Let us first consider $S_1$ and its reachability condition $S_1 \dot{S}_1 < 0$. From (3), the dynamics of the first sliding surface is given by:

$$\dot{S}_1 = \lambda_1 \dot{e}_{y_1} + \lambda_2 e_{y_1} + \lambda_3 (\dot{x}_3 - \dot{x}_1) = \lambda_1 \dot{y}_1 + \lambda_2 (y_1 - y^{1ref}) + \lambda_3 (\dot{x}_3 - \dot{x}_1)$$  \hspace{1cm} (6)

The first output is a function of the states such that $y_1 = v_t(x)$, then:

$$\dot{S}_1 = \lambda_1 \dot{y}_1 + \lambda_2 [v_t(x) - y^{1ref}] + \lambda_3 (\dot{x}_3 - \dot{x}_1)$$  \hspace{1cm} (7)

Also, the first input $u_1 = v_f$ appears in $\dot{y}_1$:

$$\dot{y}_1 = \dot{v}_t(x) = \frac{1}{2} (v_d^2 + v_q^2)^{1/2} \cdot (2v_d \dot{v}_d + 2v_q \dot{v}_q)$$  \hspace{1cm} (8)

$u_1$ specifically appears in $\dot{v}_d$ and $\dot{v}_q$:

$$\dot{v}_d = (R_e + L_e A_{11})\dot{x}_1 + L_e A_{12}\dot{x}_3 + (L_e A_{13} - L_e)(\dot{x}_2 x_5 + x_2 \dot{x}_5) + (V^\infty + L_e A_{14})\dot{x}_4 \cos(x_4 - \alpha)$$

$$\dot{v}_q = (R_e + L_e A_{33})\dot{x}_2 + (L_e A_{21} - L_e)(\dot{x}_1 x_5 + x_1 \dot{x}_5) + L_e A_{22}(\dot{x}_3 x_5 + x_3 \dot{x}_5) - (V^\infty + L_e A_{24})\dot{x}_4 \sin(x_4 - \alpha)$$  \hspace{1cm} (9)

Where it can be observed from (1) that $u_1$ appears in $\dot{x}_1$ and $\dot{x}_3$. Noteworthy, the second input $u_2$ also appears in $\dot{y}_2$ through $\dot{x}_2$ by tracking (1), (8), and (9). Hence, from (1), (7), (8), and (9), it can be concluded that the dynamics of the first sliding surface is a function of the states and both inputs and can be described in the following general form:

$$\dot{S}_1 = h_1(x, u_2) + z_1(x)u_1$$  \hspace{1cm} (10)

Consider the following controller:

$$u_1 = -[k_1(t) + \eta_1] \text{sign}(S_1)$$  \hspace{1cm} (11)

Where $k_1(t)$ is the controller gain and $\eta_1$ is a constant. The dynamics of the sliding surface in (10) now can be expanded as:

$$\dot{S}_1 = h_1(x, u_2) - z_1(x)[k_1(t) + \eta_1] \text{sign}(S_1)$$  \hspace{1cm} (12)

Define a bounded uncertainty such that:
\[ \theta_1(x, u_2) = \frac{h_1(x, u_2)}{z_1(x)} < \theta_{10} \]  

(13)

It is clear from (12) and (13) that if the controller gain is selected such that \( k_1(t) > |\theta_1(x, u_2)| \), then the reachability condition of the first sliding manifold \( S_1 \dot{S}_1 < 0 \) is achieved. Note that the gain \( k_1(t) \) is a function of time since it is adaptive, and the design of it is discussed in sections 3-3. Also, from (13), the signal of the second controller is considered an uncertainty that the first controller shall absorb. Therefore, an essential condition to secure the boundness of \( \theta_1 \) is bounding the second controller such that \( u_2 < u_{20} \) where \( u_{20} \) is a predefined constant. Next, the reachability condition of the second manifold is discussed.

2) Reachability Condition of Second Sliding Manifold

As discussed earlier, to guarantee the reachability to the surface \( S_2 = 0 \), then the condition \( S_2 \dot{S}_2 < 0 \) shall be satisfied. The dynamics of the second sliding surface defined in (4) is given by:

\[ \dot{S}_2 = \dot{e}_y_2 + \ddot{e}_y_2 \]  

(14)

Since \( e_y_2 = x_4 - y_{2\text{ref}} \) and the second derivative of \( x_4 \) is a function of \( \dot{x}_5 \), then:

\[ \dot{S}_2 = \ddot{x}_4 + \dot{x}_4 = \dot{x}_4 + \omega_r \dot{x}_5 \]  

(15)

Where the second controller \( u_2 \) appears in \( \dot{x}_5 \). Consequently, the derivative of the second sliding surface can be written in the following general structure:

\[ \dot{S}_2 = h_2(x) + z_2(x)u_2 \]  

(16)

Consider the controller:

\[ u_2 = -[k_2(t) + \eta_2]sign(S_2) \]  

(17)

Where \( k_2(t) \) is the controller gain and \( \eta_2 \) is a constant. The dynamics of the sliding surface in (16) can be then expanded as:

\[ \dot{S}_2 = h_2(x) - z_2(x)[k_2(t) + \eta_2]sign(S_2) \]  

(18)

Define a bounded uncertainty such that:

\[ \theta_2(x) = \frac{h_2(x)}{z_2(x)} < \theta_{20} \]  

(19)

It is clear from (18) and (19) that if the controller gain is selected such that \( k_2(t) > |\theta_2(x)| \), then the reachability condition of the second sliding manifold \( S_2 \dot{S}_2 < 0 \) is achieved. So far, we have proved that the reachability conditions of \( S_1 \dot{S}_1 < 0 \) and \( S_2 \dot{S}_2 < 0 \) are only guaranteed if \( k_1(t) > |\theta_1(x, u_2)| \) and \( k_2(t) > |\theta_2(x)| \). Therefore, it is required now to design these controllers’ gains, with adaptation rules, to achieve these conditions while mitigating chattering effects as much as possible.

3.3. Derivation of Controllers Gains Adaptation Rule

It is well-known that one of the main drawbacks of SMC is the associated “chattering” effects resulted from the inherent switching function within the controller [16]. Although that chattering affects the power angle and machine rotor speed (\( x_5 \)) may be acceptable, the appearance of this phenomenon in the machine terminal voltage (\( y_1 \)) and the currents (\( x_1, x_2 \) and \( x_3 \)) will cause a catastrophic impact on the power quality due to the associated harmonics with the chattering. One of the proven solutions for chattering is the adaptive scheme of SMC, and they are, for example, discussed by Utkin in [17] and by Edwards in [18]. The ASMCI incorporates an adaptive controller gain such that it is as small as possible to mitigate chattering while simultaneously guarantees a sliding motion that offsets a bounded uncertainty. Therefore, the ASMC scheme is implemented in this work and discussed in the following subsections.
The development of the adaptation rule will compose of several steps. First, an estimated equivalent controller instead of the actual will be used to develop the rule. More importantly, the controllers’ gains’ adaptation rule will have two nested adaptation layers as described in [18]. The first layer of adaptation is designed so that the gain $k$ varies with the magnitude of the sliding surface dynamics to offset the bounded uncertainty. On the other hand, the second layer will take care of the gain rate of change to guarantee that the dynamics of $k$ follow the bounded uncertainty rate of change such that $\dot{k} > \dot{x}$.

Noteworthy, since the derivation of both controllers’ gains $k_i(t)$ and $k_2(t)$ is similar, the subscript $i = 1, 2$ to represent the first and second controllers, respectively, is used henceforth for notation brevity. Also, $|q_i(x, u_i)|$ will be described as $|\dot{q}_i(x)|$ for brevity.

Let us first define the equivalent controller that will be used to derive the gains adaptation rule. To maintain sliding on the surface $S_i = \dot{S}_i = 0$, one shall have an equivalent controller that exactly cancels the bounded disturbance such that:

$$|u_{eqi}| = |\dot{q}(x)|$$  \hspace{1cm} (20)

According to Utkin in [19], this equivalent controller can be estimated as $\ddot{u}_{eqi}$ in real-time by a low-pass filter as follows:

$$\ddot{u}_{eqi} = \frac{1}{\tau} \left[ -k_i(\dot{x}) + \eta_i \text{sign}(S_i) - \ddot{u}_{eqi} \right]$$ \hspace{1cm} (21)

Where $\tau$ is a positive constant that ensures the equivalent controller estimate error $|u_{eqi} - \ddot{u}_{eqi}|$ is small. From (20) and the requirement of $k_i(\dot{x}) > |\dot{q}_i(x)|$, it is clear that the condition $k_i(\dot{x}) > |u_{eqi}|$ shall be satisfied to enforce sliding. However, since an estimate of the equivalent control is used instead of the actual, a safety margin should be introduced as follows:

$$k_i(\dot{x}) > \frac{1}{\alpha_i} |\ddot{u}_{eqi}| + \epsilon_i$$ \hspace{1cm} (22)

Where $0 < \alpha_i < 1$ and $\epsilon_i > 0$ are constants, and their selection will be discussed in sections 3-4. These constants are implemented to ensure that the controller estimates satisfy:

$$\frac{1}{\alpha_i} |\ddot{u}_{eqi}| + \frac{\epsilon_i}{2} > |u_{eqi}|$$ \hspace{1cm} (23)

And by defining an error term such that [18]:

$$\delta_i(t) = k_i(\dot{x}) - \frac{1}{\alpha_i} |\ddot{u}_{eqi}| - \epsilon_i$$ \hspace{1cm} (24)

If $\delta_i(t) \to 0$, then:

$$k_i(\dot{x}) = \frac{1}{\alpha_i} |\ddot{u}_{eqi}| + \epsilon_i$$ \hspace{1cm} (25)

From (23) and (25), it can be seen that:

$$k_i(\dot{x}) > |\ddot{u}_{eqi}| = |\dot{q}_i(x)|$$ \hspace{1cm} (26)

Hence, if it is guaranteed that $\delta_i(t) \to 0$ as $t \to \infty$, such that $k_i(\dot{x}) + \eta_i > |\dot{q}_i(x)|$, then forcing sliding motion is achieved.

Now, the two nested adaptation layers of $k_i(t)$ are derived as follows. First, we will define the adaptation of $k_i(t)$, that is the first adaptive layer, as [18]:

$$\dot{k}_i(t) = -\rho_i(t) \cdot \text{sign}[\delta_i(t)]$$ \hspace{1cm} (27)

Where $\rho_i(t)$ is a function of time and represents the upper bound of the uncertainty dynamics $|\dot{q}_i(x)| < \dot{q}_{ii}$ and it has the following form:
\[\rho_i(t) = r_{i0} + r_i(t)\]  
(28)

Where \(r_{i0}\) is a design scalar (selection of it is discussed in section 3.4) and \(r_i(t)\) is the second adaptation rule in our scheme. Assuming the uncertainty bounds are unknown (both \(q_{i0}\) and \(q_{ii}\) are unknown), the adaptation rule of \(r_i(t)\) given by [18] is:

\[
\dot{r}_i(t) = \begin{cases} 
\gamma_i|\delta_i(t)|; & |\delta_i(t)| > \delta_{i0} \\
0; & \text{otherwise}
\end{cases}
\]  
(29)

Where \(\delta_{i0} > 0\) and \(\gamma_i > 0\) are both design scalars, and their selection will be discussed in section 3.4. To allow \(r_i(t)\) tracks the rate of change of the uncertainty, we define an error function as:

\[e_i(t) = \frac{q_i q_{ii}}{a_i^2} - r_i(t)\]  
(30)

Where \(q_i > 1\) is a safety factor to ensure \(\hat{u}_{eqi} < q_i q_{ii}\).

### 3.4. Lyapunov Stability Analysis

The stability analysis is crucial to investigate the asymptotic stability of the overall closed-loop system along with the output errors. As discussed earlier, reaching the sliding manifolds and maintaining sliding guarantee asymptotically stable outputs errors and internal states of the system. However, reaching the surface can only be guaranteed if \(k_1(t) > |q_{1i}(x, u_2)|\) and \(k_2(t) > |q_{2i}(x)|\). It was also shown that these conditions are met if the error functions defined in (24) and (30) are approaching zero as \(t \to \infty\). Therefore, a reasonable candidate for a Lyapunov function is a quadratic one in terms of the sliding manifolds and errors defined in (3)-(4) and (24)-(30), respectively:

\[V = \frac{1}{2} \delta_1^2 + \frac{1}{2} \delta_2^2 + \frac{1}{2} e_1^2 + \frac{1}{2} e_2^2 + \frac{1}{2} \dot{S}_1^2 + \frac{1}{2} \dot{S}_2^2\]  
(31)

The derivative of this Lyapunov is:

\[\dot{V} = \delta_1 \dot{\delta}_1 + \frac{1}{\gamma_1} e_1 \dot{e}_1 + \delta_2 \dot{\delta}_2 + \frac{1}{\gamma_2} e_2 \dot{e}_2 + S_1 \dot{\dot{S}}_1 + S_2 \dot{\dot{S}}_2\]  
(32)

And from (31), the derivative of \(\delta_i\) for \(i = 1, 2\) is:

\[\dot{\delta}_i = k_i - \frac{1}{a_i} \hat{u}_{eqi} = -\left( r_{i0} + \frac{q_i q_{ii}}{a_i^2} - e_i \right) \text{sign}(\delta_i) - \frac{q_i q_{ii}}{a_i^2} \]  
(33)

While the derivative of \(e\) from (30) is:

\[\dot{e}_i = -\dot{r}_i\]  
(34)

Hence:

\[\delta_i \dot{\delta}_i \leq -r_{i0} |\delta_i| + \left( e_i - \frac{q_i q_{ii}}{a_i^2} \right) |\delta_i| + |\delta_i| \frac{q_i q_{ii}}{a_i^2} = -r_{i0} |\delta_i| + e_i |\delta_i|\]  
(35)

It also can be seen that \(e_i \leq \frac{q_i q_{ii}}{a_i^2}\) since \(r_i \geq 0\). Let us now examine the derivative of the Lyapunov function at both conditions of the adaption of \(r_i\) defined in (29). If \(|\delta_i| > \delta_{i0}\), then substituting (34) and (35) into (32) yields to:

\[\dot{V} = -r_{i0} |\delta_i| + e_i |\delta_i| - \frac{1}{\gamma_1} e_1 \dot{\delta}_1 - r_{20} |\delta_2| + e_2 |\delta_2| - \frac{1}{\gamma_2} e_2 \dot{\delta}_2 + S_1 \dot{\dot{S}}_1 + S_2 \dot{\dot{S}}_2\]  
(36)

Substituting (36) into (43) yields:

\[\dot{V} = -r_{i0} |\delta_i| + e_i |\delta_i| - e_i |\delta_i| - r_{20} |\delta_2| + e_2 |\delta_2| - e_2 |\delta_2| + S_1 \dot{\dot{S}}_1 + S_2 \dot{\dot{S}}_2 = -r_{i0} |\delta_i| - r_{20} |\delta_2| + S_1 \dot{\dot{S}}_1 + S_2 \dot{\dot{S}}_2\]  
(37)
If $|\delta| < \delta_0$, then $\dot{r}_i = 0$ and $e_i < 0$ since $r_i \geq \frac{q_i \delta_i}{\alpha_i}$, hence from (36) also:

$$V = -r_{10} |\delta_1| + e_1 |\delta_1| - r_{20} |\delta_2| + e_2 |\delta_2| + S_1 \hat{S}_1 + S_2 \hat{S}_2$$

(38)

Since the error terms in the Lyapunov derivative in (37) and (38) at both values of $\dot{r}_i$ are negative, then $\delta_i, e_i \to 0$ as $t \to \infty$. Consequently, the condition $k_i(t) > |q_i(x)|$ is achieved, and as a result, the terms $S_1 \hat{S}_1$ and $S_2 \hat{S}_2$ in (37) and (38) are both negative. Therefore, the derivative of this Lyapunov is semi-negative definite since $V(0) = 0$. However, at $\delta_i = e_i = S_i = 0$, the sliding on the manifolds is attainable and maintained, resulting in stable output errors and internal states as discussed in sections 3.1 and 3.3. Since this is the case and $V$ is radially unbounded positive definite, then the output errors and the system's internal states are asymptotically stable under the condition of bounded uncertainties defined by $q_{i0}$ and $q_{ii}$.

Remarks

- From (37) and (38), the selection of $r_{i0}$ constitutes the decaying rate of the gain errors defined in (24) and consequently how fast the states and outputs errors trajectories will start moving toward the sliding manifolds.
- The controllers' coefficients $e_i, \alpha_i, \delta_{i0}$ and $y_i$ shall be selected such that:

$$\frac{1}{4} e_i^2 > \frac{\delta_{i0}^2}{y_i} + \frac{1}{\alpha_i} \left( q_i q_{ii} \right)^2$$

(39)

to guarantee asymptotic stable gain errors, defined in (24) and (30), and to secure bounded controllers' gains [18].

4. Simulation and discussion

The simulation is carried out on the SMIBS shown in Fig. 1 with two different closed-loop control systems. The first governs our design shown in Fig. 2, while the second is a conventional SMC with constant gains for performance comparison. The main objective of the simulation is to verify the effectiveness of the designed ASMC in terms of chattering mitigation and to assess its capability in achieving asymptotic stable output errors and stabilizing the systems' internal states, such that $\lim_{t \to \infty} e_x = 0$ and $\lim_{t \to \infty} x = x_f$, under the presence of severe disturbance. The disturbances defined previously by $q_1(x, u_2)$ and $q_2(x)$ will also be "momentarily" perturbed during the simulation by altering the infinite bus voltage, that is, in particular, altering the parameter $V^\infty$. With this, we eventually simulate a short circuit fault on the SM bus that is cleared within finite time. We then assess the system's overall closed-loop performance under such severe conditions and compare it with conventional SMC.

4.1. Scenario

The duration of the simulation is 380 tu (this is around a second). A three-phase fault occurs at 150 tu in the power system's bus, at the location indicated in Fig. 1, and the fault is cleared at 190 tu (fault duration is around 40 tu, which is equivalent to 100 msec). As indicated previously, this system fault is simulated by altering the value of $V^\infty$. In this case, its value will be reduced from 1.0 to 0.5 during the fault only; when the fault is cleared, $V^\infty$ returns to its nominal value of 1.0. For the output references $y_{1 \text{ref}}$ and $y_{2 \text{ref}}$, a reasonable selection is 1.0 and 0.15 rad, respectively. For $y_{1 \text{ref}}$, since the SM is connected to an infinite bus with $V^\infty = 1.0$ nominal, then the SM is expected to operate at the same voltage level during a steady-state condition. On the other hand, $y_{2 \text{ref}}$, the power angle of the SM should be positive since the SM is running on generation mode.

The sliding manifolds and the controller coefficients are selected based on the discussions in sections 3.1 and 3.4, respectively, and their values are depicted in Table 3. Note that $y_{1}, y_{2}$ are both chosen to be sufficiently large, and $\alpha_1, \alpha_2$ are set at the high side of their allowable range to ensure reducing the right-hand side of inequality (39), and hence the inequality is
satisfied. The values of $\delta_{10}, \delta_{20}$ are adjusted to be as small as possible while at the same time avoiding any potential computational errors during simulation, as suggested in [18]. For the SMC gains, they are selected to be sufficiently large to offset the unseen disturbances. The parameters' values of the nonlinear SMIBS model, $A_{ij}$ and $B_{ij}$, are shown in Table 4. As indicated previously, these values are functions of the system’s components.

4.2. Results

All results of the simulation during and after the fault are represented in plots. The internal states of the system are shown in Fig. 3, while the outputs are shown in Fig. 4. Also, the controllers’ signals are shown in Fig. 6; meanwhile, the ASMC gains are reported in Fig. 5. The sliding manifolds are illustrated in Fig. 7. Finally, the trajectories of electrical states $x_1, x_2, x_3$ are shown in Fig. 8, the trajectories of the mechanical states $x_4, x_5$ are depicted in Fig. 9, and the output errors are in Fig. 10.

| Coefficient | Assignee       | Value |
|-------------|----------------|-------|
| $\lambda_1$ | First Sliding Manifold | 1.00  |
| $\lambda_2$ | First Sliding Manifold | -1.00 |
| $\lambda_3$ | First Sliding Manifold | 10.0  |
| $\epsilon_{1, 2}$ | ASMC       | 0.01  |
| $\delta_{10}, \delta_{20}$ | ASMC       | 0.05  |
| $\eta_{1, 2}$ | ASMC       | 0.5   |
| $\gamma_{1, 2}$ | ASMC       | 0.99  |
| $\tau$ | ASMC       | 400   |
| $k_1$ | SMC       | 0.05  |
| $k_2$ | SMC       | 5.00  |

Table 3. Sliding manifolds and controllers' coefficients values

| Parameter | Value     | Parameter | Value     | Parameter | Value     |
|-----------|-----------|-----------|-----------|-----------|-----------|
| $A_{11}$  | -0.173    | $A_{23}$  | 0.06128   | $A_{21}$  | 0.00939   |
| $A_{12}$  | -0.000734 | $A_{24}$  | -0.3049   | $A_{22}$  | -0.2958   |
| $A_{13}$  | 2.823     | $A_{21}$  | -0.1994   | $A_{31}$  | -0.3136   |
| $A_{14}$  | -0.8607   | $A_{12}$  | -0.001297 | $B_{13}$  | 0.9919    |
| $A_{21}$  | -1.018    | $A_{13}$  | 3.253     | $B_{31}$  | 1.753     |
| $A_{22}$  | 0.5762    | $A_{14}$  | -0.9919   | $B_{52}$  | 0.1565    |

Table 4. SMIBS parameters’ values

4.3. Discussion

The system’s internal states and outputs, depicted in Fig. 3 and Fig. 4, respectively, are asymptotically stabilized after the fault clearance with almost similar performance observed with ASMC and SMC. That asymptotic stability is also indicated by the electrical and mechanical states trajectories depicted in Fig. 8 and Fig. 9, respectively. Although the overshooting observed within the electrical states are acceptable, around rated values of 1, the oscillations are rather high. On the other hand, a remarkable performance of the controllers, ASMC and SMC, can be observed in the mechanical states as their dynamic response during the fault was negligible; this is also seen in their trajectories shown in Fig. 9. For the input-output responses depicted in Fig. 4, the controllers could successfully force them to follow the reference signals after clearing the fault at 190 tu, proving the asymptotic stability of the output errors discussed in section 3.4. The errors’ trajectories depicted in Fig. 10 also confirm this as they settle at zero. Noteworthy, the dynamic response of the first output experienced large momentarily overshoot and oscillation when the fault was cleared. Although that response may affect the SM’s windings insulation, the overshoot (or voltage surge in power system terminology) is expected when the infinite bus voltage is restored to its nominal value. This is attributed to the
difference in the machine terminal and bus voltages at the instant of bus voltage restoration. On the other hand, the dynamic performance of the second output is superior.

Although both ASMC and SMC achieve similar states and outputs dynamic performance, a dichotomy in their performance is observed in their signals, which can be seen in Fig. 6. The chattering seen in the SMC signal is significant, while our design of the ASMC mitigates it. Reducing chattering in the SMIBS controllers is vital to extend the system's physical components' lifetime; this includes both excitation and governor systems. This satisfactory performance results from the adaptive gains reported in Fig. 5, where we can see how the gains vary in response to the disturbance introduced into the system. In that sense, the designed adaptation rules could successfully adjust the gains, resulting in offsetting the disturbance and simultaneously mitigating the chattering phenomenon.

The sliding manifolds shown in Fig. 7 reveal that the SMC and the ASMC both reach the manifolds and maintain sliding even during the presence of a system’s fault. We can observe that the switching of the first surface is more than that of the second manifold. That can be attributed to the high nonlinearity inherent in its uncertainty term defined in (13), where this term is a function of the first output dynamics, defined in (8), and the second input.

Overall, the performance of the ASMC is satisfactory as it was proven that, with its two nested adaptive layers scheme, it could force the trajectories of the states and the output errors to the sliding manifolds during the presence of severe disturbance. That indeed also verifies the stability analysis conducted previously, where it was shown that the output errors are asymptotically stable, and all internal states are reaching finite values as \( t \to \infty \). Besides the successful dynamic performance, the ASMC outperforms the SMC in terms of mitigating the chattering phenomenon. That is attributed to the ASMC’s capability in adaptively adjusting the gains in response to the disturbance rather than the stationary gain SMC gains.

5. Conclusion

Modeling of Synchronous Machine (SM) can be performed with various approaches that depend significantly on the main objective of their development. This work aims to design a stable closed-loop system that can efficiently handle large disturbances such as faults occurring at the power system bus. Consequently, the model selected for the analysis is a MIMO 5th order nonlinear model representing the dynamics of a SMIBS. The model composes of two sub-models, electrical and mechanical sub-models. To handle the SMIBS's wild uncertainties, including nonlinearities and severe disturbances, an Adaptive Sliding Mode Control (ASMC) is designed with gains of two nested adaptive layers. The robustness of this ASMC is that it neither requires prior knowledge about uncertainties nor an explicit estimation through observer-based controllers. The simulation results of the closed-loop system with the ASMC proved its effectiveness and verified the conducted theoretical stability analysis. We saw that the controllers could successfully achieve asymptotic stable outputs error and stabilizing the SMIBS internal states during large disturbances. Most importantly, the ASMC outperforms the SMC in terms of mitigating the chattering phenomenon. That is attributed to the ASMC's capability in adaptively adjusting the gains in response to the disturbance rather than the stationary gain SMC gains.

Yet, as future work, we believe that the performance of the designed controllers can still be improved, especially enhancing the dynamic performance. We, therefore, recommend exploring the control design of Edwards et al. in [27], where they present HOSM control laws to prevent overestimating the gains of the adaptive scheme. In addition, we see that the work of Roy et al. in [28] is worths investigating. They propose an ASMC design that does neither require a priori knowledge about the uncertainties nor their upper bounds, which ultimately enhances the robustness of the controller’s performance.
