Retinal lipid and glucose metabolism dictates angiogenesis through the lipid sensor Ffar1

Tissues with high metabolic rates often use lipids, as well as glucose, for energy, conferring a survival advantage during feast and famine1. Current dogma suggests that high-energy–consuming photoreceptors depend on glucose2,3. Here we show that the retina also uses fatty acid β-oxidation for energy. Moreover, we identify a lipid sensor, free fatty acid receptor 1 (Ffar1), that curbs glucose uptake when fatty acids are available. Very-low-density lipoprotein receptor (Vldlr), which is present in photoreceptors4, and is expressed in other tissues with a high metabolic rate, facilitates the uptake of triglyceride-derived fatty acid5,6. In the retinas of Vldlr−/− mice with low fatty acid uptake5 but high circulating lipid levels, we found that Ffar1 suppresses expression of the glucose transporter Glut1. Impaired glucose entry into photoreceptors results in a dual (lipid and glucose) fuel shortage and a reduction in the levels of the Krebs cycle intermediate α-ketoglutarate (α-KG). Low α-KG levels promotes stabilization of hypoxia-induced factor 1a (Hif1α) and secretion of vascular endothelial growth factor A (Vegfa) by starved Vldlr−/− photoreceptors, leading to neovascularization. The aberrant vessels in the Vldlr−/− retinas, which invade normally avascular photoreceptors, are reminiscent of the vascular defects in retinal angiomatous proliferation, a subset of neovascular age-related macular degeneration (AMD)7, where high circulating lipid levels, we found that Ffar1 suppresses expression of the glucose transporter Glut1. Impaired glucose entry into photoreceptors results in a dual (lipid and glucose) fuel shortage and a reduction in the levels of the Krebs cycle intermediate α-ketoglutarate (α-KG). Low α-KG levels promotes stabilization of hypoxia-induced factor 1a (Hif1α) and secretion of vascular endothelial growth factor A (Vegfa) by starved Vldlr−/− photoreceptors, leading to neovascularization. The aberrant vessels in the Vldlr−/− retinas, which invade normally avascular photoreceptors, are reminiscent of the vascular defects in retinal angiomatous proliferation, a subset of neovascular age-related macular degeneration (AMD)7, where high glucose and glucose photoreceptor energy metabolism may therefore be a driving factor in macular telangiectasia, neovascular AMD and other retinal diseases.

Retinal angiomatic proliferation (RAP) is observed in macular telangiectasia (MacTel)8, as well as in 15–20% of cases of neovascular AMD7, the leading cause of blindness in older adults9. Photoreceptors, which are densest in the macula, are among the highest energy-consuming and mitochondria-rich cell types2,10, suggesting the hypothesis that insufficient energy production for the high-energy demands of photoreceptors contributes to macular neovascularization. VEGFA contributes to retinal neovascularization, but factors that initiate VEGFA secretion in macular disease remain mostly unknown. We hypothesized that disordered photoreceptor mitochondrial energy metabolism might drive aberrant angiogenesis in the normally avascular photoreceptors in an attempt to increase fuel supply, consistent with the observation that dyslipidemia and mitochondrial dysfunction (which are associated with aging) are important risk factors for neovascular AMD9.

Retinal neurons are thought to rely on glucose for fuel2,3. Glucose is metabolized to pyruvate (by glycolysis) and either converted to lactate in the cytoplasm or oxidized to acetyl-CoA in mitochondria before entering the Krebs cycle to produce ATP. In photoreceptors, the major glucose transporter is solute carrier family 2 (facilitated glucose transporter), member 1 (Slc2a1; also known as Glut1)11,12. Clinically, SLC2A1 (hereafter referred to as GLUT1) deficiency causes infantile seizures and developmental delay13, highlighting the importance of glucose metabolism in the brain. However, GLUT1-deficient individuals have normal vision, suggesting the use of alternative retinal energy substrates, perhaps through lipid β-oxidation.

Lipid β-oxidation commonly occurs in the heart and skeletal muscle (tissues with high metabolic rates), where abundant amounts...
of VLDLR facilitate fatty acid uptake\textsuperscript{4,4}. VLDLR binds chylomicrons and enables cleavage of long-chain fatty acids from triglycerides by lipoprotein lipase\textsuperscript{4}. Vldlr is involved in the transcytosis of active lipoprotein lipase across endothelial cells\textsuperscript{15}, enabling the delivery of free fatty acid to tissue. Vldlr contributes to lipid uptake and fatty acid β-oxidation in the heart\textsuperscript{5}. Because lipid β-oxidation enzymes are expressed in the eye\textsuperscript{16}, we hypothesized that fatty acid β-oxidation is used for energy in lipid- and Vldlr-rich photoreceptors. VLDLR deletion causes maculopathy in humans\textsuperscript{17}, and Vldlr\textsuperscript{−/−} mice develop RAP-like retinal vascular lesions (Fig. 1a\textsuperscript{c}). Study of Vldlr\textsuperscript{−/−} mice thus allows for the exploration of the hypotheses that lipids fuel photoreceptors and that fuel deficiency promotes neovessel formation.

We first tested whether there was a link between the number of RAP-like lesions and photoreceptor energy demand. Rod photoreceptors consume 3–4 times more energy in darkness than in light to maintain the ‘dark current’, an electrochemical gradient required for photon-induced polarization\textsuperscript{10}. Conversely, membrane turnover and visual cycle activity are decreased in darkness\textsuperscript{10}. Dark-raised Vldlr\textsuperscript{−/−} mice developed 1.5-fold more RAP-like vascular lesions than light and dark–raised mice (Fig. 1b), suggesting that energy metabolism influences neovascular disease. Photoreceptors mature from the optic nerve outward toward the periphery, and energy consumption increases as photoreceptors mature\textsuperscript{2,18}. In retinas from postnatal day 16 (P16) Vldlr\textsuperscript{−/−} mice, the more mature central retina had more RAP-like lesions than the peripheral retina (Fig. 1b), consistent with this model.

To determine whether loss of Vldlr specifically in photoreceptors is sufficient to drive pathological vessel formation, we knocked down expression of Vldlr in the photoreceptors of Vldlr\textsuperscript{−/−}/− mice, which have normal circulating fatty acid levels and do not have a RAP-like phenotype\textsuperscript{19}. To knock down Vldlr expression selectively in photoreceptors, we used an adenov-associated virus (AAV) 2–derived hRK construct, which contains a photoreceptor-specific human rhodopsin kinase gene (GRK1) promoter driving the expression of shRNA that targets Vldlr expression. Loss of Vldlr expression in photoreceptors led to the development of RAP-like lesions (Supplementary Fig. 1).

Consistent with the concept that Vldlr\textsuperscript{−/−} photoreceptors are energy deficient, they had swollen mitochondria, as assessed by three-dimensional (3D) scanning electron microscopy (Fig. 1c and Supplementary Videos 1 and 2). Moreover, retinas from Vldlr\textsuperscript{−/−} mice had reduced ATP stores (Fig. 1d), confirming an energy deficit.

To explore the mechanistic basis of the photoreceptor energy deficit, we examined the contribution of fatty acids and glucose to energy production in wild-type (WT) retinas (Supplementary Fig. 2a). The long-chain fatty acid palmitate fueled mitochondrial β-oxidation in retinal explants, doubling the oxygen-consumption rate (OCR); moreover, treatment with etomoxir, which inhibits fatty acid transport into mitochondria, abrogated palmitate-induced mitochondrial respiration, confirming that fatty acid β-oxidation contributes to retinal energy metabolism (Fig. 2a and Supplementary Fig. 2a–c). We also examined the contribution of glucose oxidation and found that retinal glucose could be oxidized by mitochondria as efficiently as a fatty acid (Supplementary Fig. 2d–f). However, as reported by Warburg, Cohen and Winkler\textsuperscript{3,20}, the vast majority of glucose (87%) was converted to lactate by glycolysis rather than being used for oxidative phosphorylation (Supplementary Fig. 2g). Unlike retinas from WT mice, those from Vldlr\textsuperscript{−/−} mice (i.e., with limited fatty acid uptake) did not increase mitochondrial respiration after exposure to palmitate (Supplementary Fig. 2h). Therefore, in addition to glucose, fatty acids contribute to retinal energy production, which may be deficient in retinas from Vldlr\textsuperscript{−/−} mice.

Given the possible role of VLDLR in retinal lipid energy metabolism, we quantified retinal fatty acid uptake. Consistent with a previous report\textsuperscript{21}, Vldlr was highly expressed in retinal photoreceptors (Supplementary Fig. 3a), and uptake of long-chain fatty acids was reduced in retinas from Vldlr\textsuperscript{−/−} mice (Supplementary Fig. 3b,c). Serum turbidity reflected higher circulating lipid levels in Vldlr\textsuperscript{−/−} versus WT mice (Supplementary Fig. 3b,c). Plasma levels of triglycerides and medium- and long-chain fatty acids (particularly palmitate) were elevated in Vldlr\textsuperscript{−/−} mice as compared to WT mice (Fig. 2c and Supplementary Fig. 3d,e). Notably, fatty acid β-oxidation of lipids to produce acetyl-CoA in mitochondria was suppressed in retinas from Vldlr\textsuperscript{−/−} mice (Fig. 2d), and total
acetyl carnitine levels, as well as free carnitine levels, were reduced in Vldlr−/− mice, as measured by LC-MS/MS. Basal indicates initial OCR without treatment; leak indicates OCR independent of ATP production, after addition of oligomycin to induce a proton leak; max indicates maximal OCR, after addition of FCCP (carbonyl cyanide-p-trifluoromethoxyphenylhydrazone). Treatment with rotenone + antimycin A (RAA) reveals nonmitochondrial respiration. (c) Circulating levels of palmitate in the plasma of WT (n = 7) and Vldlr−/− (n = 13) mice. (d) Metabolite array to assess the levels of fatty acid β-oxidation metabolites in the retinas of WT and Vldlr−/− mice (n = 3 mice per group; each column represents one mouse retina). (e) Total amount of acetyl carnitine (P = 0.0108) (left) and levels of free carnitine (P = 0.0014) (right) in retinas from WT and Vldlr−/− mice, as measured by LC-MS/MS (n = 3 retinas per group). (f) qRT-PCR analysis for Cpt1a expression in intact WT and Vldlr−/− retinas (P = 0.0052) (left) and in retinal layers after laser-capture microdissection (LCM) (right) (n = 3 retinas per group). ONL, outer nuclear layer (photoreceptors); INL, inner nuclear layer; GCL, ganglion cell layer. (g) Representative [18F]FDG microPET and computed tomography images of retinas from WT (left) and Vldlr−/− (middle) mice and quantification of [18F]FDG uptake (right) (WT, n = 22; Vldlr−/−, n = 12 retinas; P = 0.0116). The color bar represents the range of [18F]FDG uptake from minimum (blue) to maximum (red) uptake. Scale bar, 4 mm. (h) qRT-PCR analysis for Slc2a1 (Glut1) expression in intact retinas (WT, n = 9; Vldlr−/−, n = 12; P = 0.0119) (left) or in retinal layers after LCM (n = 3 retinas per group) (right). (i) Quantification of Glut1 protein expression in intact retinas from WT and Vldlr−/− mice (n = 6 retinas per group; P = 0.030) (left) from immunoblots (representative blots shown on right). Throughout, results are presented as mean ± s.e.m. *P < 0.05, **P < 0.01, ***P < 0.001; by two-tailed Student’s t-test (c-f, g-i) or one-way analysis of variance (ANOVA) with Tukey post hoc analysis (b, f, h).

Figure 2: Dual lipid and glucose fuel deficiency in Vldlr−/− retinas. (a, b) OCR (a) and calculated maximal OCR (b) of WT retinas treated with the long-chain fatty acid palmitate or BSA (Ctl) in the presence of a DMSO control (Veh) or etomoxir (40 μM) (number of retinas evaluated: Ctl, n = 7; Ctl + etomoxir, n = 7; palmitate, n = 6; palmitate + etomoxir, n = 8). Basal indicates initial OCR without treatment; leak indicates OCR independent of ATP production, after addition of oligomycin to induce a proton leak; max indicates maximal OCR, after addition of FCCP (carbonyl cyanide-p-trifluoromethoxyphenylhydrazone). Treatment with rotenone + antimycin A (RAA) reveals nonmitochondrial respiration. (c) Circulating levels of palmitate in the plasma of WT (n = 7) and Vldlr−/− (n = 13) mice. (e) Total amount of acetyl carnitine (P = 0.0108) (left) and levels of free carnitine (P = 0.0014) (right) in retinas from WT and Vldlr−/− mice, as measured by LC-MS/MS (n = 3 retinas per group). (f) qRT-PCR analysis for Cpt1a expression in intact WT and Vldlr−/− retinas (P = 0.0052) (left) and in retinal layers after laser-capture microdissection (LCM) (right) (n = 3 retinas per group). ONL, outer nuclear layer (photoreceptors); INL, inner nuclear layer; GCL, ganglion cell layer. (g) Representative [18F]FDG microPET and computed tomography images of retinas from WT (left) and Vldlr−/− (middle) mice and quantification of [18F]FDG uptake (right) (WT, n = 22; Vldlr−/−, n = 12 retinas; P = 0.0116). The color bar represents the range of [18F]FDG uptake from minimum (blue) to maximum (red) uptake. Scale bar, 4 mm. (h) qRT-PCR analysis for Slc2a1 (Glut1) expression in intact retinas (WT, n = 9; Vldlr−/−, n = 12; P = 0.0119) (left) or in retinal layers after LCM (n = 3 retinas per group) (right). (i) Quantification of Glut1 protein expression in intact retinas from WT and Vldlr−/− mice (n = 6 retinas per group; P = 0.030) (left) from immunoblots (representative blots shown on right). Throughout, results are presented as mean ± s.e.m. *P < 0.05, **P < 0.01, ***P < 0.001; by two-tailed Student’s t-test (c-f, g-i) or one-way analysis of variance (ANOVA) with Tukey post hoc analysis (b, f, h).
of the gene encoding pyruvate kinase (Pkm), which is a critical enzyme in glycolysis, was observed in Vldlr−/− retinas in the microarray experiment and confirmed by qRT-PCR (Supplementary Fig. 6b). Expression of the Slc2a3 (Glut3) and Slc2a4 (Glut4) proteins was not affected (Supplementary Fig. 6c). Hence, Vldlr−/− retinas display both lipid- and glucose-uptake defects, consistent with a generalized energy shortage.

We posited that since the lipid-uptake deficiency in Vldlr−/− retinas, the increased abundance of lipids in serum from Vldlr−/− mice might signal through lipid sensors to reduce glucose uptake, as a means to control fuel supply to the retina (Fig. 3a). Of the known fatty acid-sensing G protein-coupled membrane receptors (GPCRs) we screened in WT retinas, Ffar1 was the most abundantly expressed, and its expression level was increased further in retinas from Vldlr−/− mice, particularly in photoreceptors (Fig. 3b,c). Ffar1, first discovered in the pancreas24, governs glucose transport and insulin secretion in pancreatic islet beta cells25,26. High expression of Ffar1 in the pancreas suppresses expression of Slc2a2 (Glut2), the main endocrine pancreas glucose transporter27. Ffar1 has also been localized in the brain, where its function is not well characterized28,29. In WT and Vldlr−/− retinas, we found that treatment with a Ffar1 agonist (GW9508) suppressed expression of Glut1 (ref. 12) and retinal glucose uptake (Fig. 3d,e and Supplementary Fig. 7a). Notably, treatment of Vldlr−/− mice with GW9508 more than doubled the number of RAP-like lesions, as compared to those in untreated controls (Fig. 3f).

Ffar1 binds lipids that contain >6 carbon atoms29. Vldlr−/− mice treated with medium-chain triglycerides (MCT; 8–10 carbon atoms), which are Ffar1 agonists29, or with the Ffar1-selective agonist TAK-875 (ref. 30) had a further decrease in the level of retinal Glut1 expression and more RAP-like lesions, as compared to untreated controls (Supplementary Fig. 8). Next we generated mice that were deficient in both Vldlr and Ffar1. Retinas from Vldlr−/−Ffar1−/− mice had increased glucose uptake and increased Glut1 expression at the mRNA and protein levels, as compared to those from Vldlr−/− mice (Fig. 3g,h, Supplementary Fig. 7b,c and Supplementary Video 3). Vldlr−/−Ffar1−/− mice also had fewer RAP-like lesions than Vldlr−/− mice (Fig. 3i). In vitro, knockdown of Ffar1 or treatment with the mitogen-activated protein kinase (MAPK) kinase inhibitor PD98059 prevented the suppression of Glut1 expression by GW9508 treatment in 661W photoreceptor cells (Supplementary Fig. 7d–f). Therefore, Ffar1 may act as a nutrient sensor, coupling mitochondrial metabolism with the availability of circulating substrates.

We hypothesized that photoreceptors challenged by a deficiency of both glucose and lipid substrates would signal to increase vascular supply in an attempt to restore energy homeostasis (Fig. 4a). Hypoxia has been assumed to be the main driver of angiogenesis, but inadequate nutrient availability to tissue might also control blood vessel growth. As compared to WT retinas, Vldlr−/− retinas had reduced levels of pyruvate (a metabolic intermediate that feeds into the Krebs cycle), acetylcarnitine (which provides an estimation of acetyl-CoA...
levels) and α-KG (Fig. 4b–d). Together with oxygen, α-KG is a necessary co-activator of prolyl-hydroxylase dehydrogenase (PHD), the enzyme that tags Hif1α for degradation by proline hydroxylation. A decreased level of hydroxyproline was detected in Vldlr−/− retinas as compared to WT retinas (Fig. 4e), consistent with reduced PHD activity. Indeed, the reduction in retinal glucose uptake in 661W photoreceptor cells that was induced by GW9508 treatment or by glucose starvation was associated with Hif1α stabilization (Supplementary Fig. 9a–c) and Vegfa secretion (Supplementary Fig. 9d,e). In vivo, Hif1α stabilization in Vldlr−/− photoreceptors (Fig. 4f,g) was associated with increased Vegfa production (Fig. 4h,i). Concurrent Ffar1 and Vldlr deficiency reversed this effect and decreased Hif1α and Vegfa levels (Fig. 4f,h), which was associated with fewer vascular lesions (Fig. 3i).

Increased expression of Vegfa from photoreceptors is sufficient to promote RAP-like lesions. Mice engineered to secrete Vegfa in photoreceptors develop RAP comparable to that in Vldlr−/− mice22.

There may be other mechanisms of Hif1α stabilization. Notably, the oxidative stress associated with an energy crisis may directly stabilize Hif1α and promote Vegfa secretion from Vldlr−/− photoreceptors,43,34 potentially contributing to vascular lesion formation. Although macrophages are often implicated in the etiology of AMD, we did not find evidence for their association with the onset of nascent RAP-like lesion development in retinas from Vldlr−/− mice; we also observed that macrophages surrounded mature but not immature lesions (Supplementary Fig. 10). To translate these findings to human disease, we measured vitreous VEGFA levels in human subjects with AMD (either those with macular hole, n = 8). Results are presented as mean ± s.e.m. *P < 0.05, **P < 0.01, ***P < 0.001; by two-tailed Student’s t-test (c,d), Mann-Whitney U test (b,e) or one-way ANOVA with post hoc Dunnett’s (f,j) or Tukey’s multiple comparison (h).
In the retina, the ability to use both lipids and glucose as fuel might be beneficial in periods of high fuel need or fuel deprivation. Fasting liberates fatty acid from adipose tissue, which is used by high-energy-consuming organs capable of fatty acid β-oxidation, such as the heart and perhaps the retina. Indeed, disorders of fatty acid β-oxidation are associated with retinopathy. Moreover, Ppara agonists that increase fatty acid β-oxidation have been used successfully to prevent diabetic proliferative retinopathy and, further exploration of the role of Ppara in metabolic signaling in neovascular eye disease is warranted. Overall, our findings suggest that lipids are an energy substrate in the retina, challenging the current dogma that glucose is the only fuel for photoreceptors.

Tissues that use lipid as fuel curb glucose uptake during starvation; thus, the capacity to sense nutrient availability and adapt fuel uptake accordingly might improve metabolic efficiency. GPCRs are known membrane sensors for the availability of amino acids, glucose and lipids. Here we show that Ffar1 is a metabolic sensor of fatty acid availability, which controls glucose entry into the retina. We speculate that long-term suppression of glucose entry by Ffar1 in photoreceptors (perhaps secondary to increased levels of circulating lipids) might contribute to age-related mitochondrial dysfunction in AMD or MacTel. The retinal effects of Ffar1 agonists, which are currently being considered for the treatment of type 2 diabetes, should be carefully monitored, particularly in older individuals who are at an increased risk for AMD.

Dysregulated mitochondrial metabolism might contribute to pathological angiogenesis in other diseases, such as cancer. Viewed in this context, the Warburg effect—in which suppressed mitochondrial oxidative phosphorylation leads to lower levels of α-KG—promotes angiogenesis at the cost of efficient ATP production. Decreased levels of α-KG would decrease PHD activity, leading to Hif1a stabilization, which would drive tumor angiogenesis. Our findings suggest the importance of mitochondrial fuel starvation as a driver of angiogenesis, matching energy demands with vascular supply. With a decline in mitochondrial function with age, this process may contribute to pathological angiogenesis in diseases associated with aging retina.

In summary, we show that lipid uptake and lipid β-oxidation are curtailed in Vldlr−/− retinas. Increased levels of circulating fatty acids can activate Ffar1, leading to decreased retinal glucose uptake and decreased levels of the Krebs cycle intermediate α-KG. Consequently, Hif1a is stabilized and Vegfa is secreted by Vldlr−/− photoreceptors, giving rise to pathologic RAP-like neovessels. This study highlights three new mechanistic insights into retinal physiology and neovascular AMD–RAP: (i) lipid β-oxidation is an energy source for the retina; (ii) Ffar1 is an important nutrient sensor of circulating lipids that controls retinal glucose entry to match mitochondrial metabolism with the available fuel substrates; and (iii) nutrient scarcity is a driver of pathological angiogenesis in the retina. These insights may thus contribute to the discovery of new treatments for retinal disease.

ONLINE METHODS

Mice. All studies adhered to the NIH Guide for the Care and Use of Laboratory Animals and the Association for Research in Vision and Ophthalmology (ARVO) Statement for the Use of Animals in Ophthalmic and Vision Research (http://www.arvo.org/About_ARVO/Policies/Statement_for_the_Use_of_Animals_in_Ophthalmic_and_Visual_Research/) and were approved by the Institutional Animal Care and Use Committee at Boston Children’s Hospital. Vldlr-knockout mice (Vldlr−/−; Jackson Lab stock: 002529) were crossed with wild-type C57BL/6 mice to obtain heterozygous breeders for littermate-controlled experiments. Vldlr−/− mice were also crossed with Ffar1-knockout (Ffar1−/−) mice to ultimately obtain Vldlr−/−Ffar1−/− heterozygous breeders and double-knockout mice (Vldlr−/−Ffar1−/−). Pups weighing <5 g or >7 g at postnatal day (P)16 were excluded. Littermate Vldlr−/− pups were treated from P8 to P15 with WY146436 (30 mg per kg body weight (mg/kg) once daily; by intraperitoneal injection (i.p.); Sigma), GW9508 (14 µM, once daily; i.p.; Cayman), TAK-875 (15 mg/kg twice daily; by gavage; Selleckchem), medium-chain triglyceride oil (MCT; 20 µl once daily; by gavage); Nestle) and the corresponding vehicle were sacrificed at P16 to quantify retinal vascular lesions. Mouse pups of both genders were used.

Quantification of vascular lesions. For quantification of outer retina vascular lesions, which are reminiscent of retinal angiomatous proliferation (RAP) or macular telangiectasia (MacTel), mice were euthanized with a mixture of xylazine and ketamine. Eyes were enucleated and fixed in 4% paraformaldehyde or macular telangiectasia (MacTel), mice were euthanized with a mixture of xylazine and ketamine. Eyes were enucleated and fixed in 4% paraformaldehyde and then providing BSA (control) or a BSA-palmitate conjugate (Seahorse). Glucose oxidation rates were determined by treating tissues or cells with etomoxir (40 µM) for 1 hour before taking measurements. Fatty acid oxidation rates were determined with 14C-labeled 2-bromopalmitate tracer injected twice daily (i.p.; 0.5 µg per dose) from P9 to P12; the total administered radioactivity was normalized for mouse body weight. Retinas were then dissected and homogenized in Ultima Gold liquid scintillation cocktail (PerkinElmer) and beta-counted (14C disintegration per minute or DPM) using a Tri-Carb 2900TR instrument (PerkinElmer), correcting for background scintillation.

ATP measurements. ATP was measured using a kit, as per the instruction manual (Molecular Probes, A22066). Briefly, a standard reaction solution was made from the following components: dH2O, 20mM Reaction Buffer, DTT (0.1 M), d-luciferin (10 mM), and firefly luciferase stock solution (5 mg/ml). Low-concentration ATP standard solutions were prepared by diluting ATP solution (5 mM) in dH2O. A standard curve was created by subtracting the background luminescence of the standard reaction solution from luminescence readings for a series of dilute ATP standard solutions. Luminescence measurements were taken for ATP-containing samples, and the amount of ATP in experimental samples was calculated from the standard curve.

Oxygen-consumption rates and extracellular-acidification rates. All oxygen-consumption rates (OCRs) were measured using a Seahorse XF96 Flux Analyzer. Whole retinas were isolated and 1-mm punch biopsies were loaded into a 96-well plate. Retinal punches were incubated in assay medium (Dulbecco’s modified Eagle’s medium (DMEM) 5030 supplemented with 12 mM glucose, 10 mM HEPES and 26 mM NaHCO3) to measure OCRs and extracellular acidification rates (ECARs). Photoreceptor (661W) cells were incubated in assay medium (DMEM 5030, 12 mM glucose, 10 mM HEPES) 1 hour before taking measurements. Fatty acid oxidation rates were determined with 14C-labeled 2-bromopalmitate tracer injected twice daily (i.p.; 0.5 µg per dose) from P9 to P12; the total administered radioactivity was normalized for mouse body weight. Retinas were then dissected and homogenized in Ultima Gold liquid scintillation cocktail (PerkinElmer) and beta-counted (14C disintegration per minute or DPM) using a Tri-Carb 2900TR instrument (PerkinElmer), correcting for background scintillation.

Scanning electron microscopy and three-dimensional (3D) retinal reconstruction. Tissue was processed for serial block-face scanning electron microscopy (SEM) using an adapted version of a protocol established by Deerinck et al. Whole eyes were isolated and fixed in Karynovsky’s fixative. The cornea and lens were removed and the tissue was further fixed in tannic acid overnight. Heavy-metal infiltration was then undertaken; tissue was incubated in 1.5% potassium ferrocyanide and 0.5% osmium tetroxide in cacodylate buffer, followed by thio-carbohydrazide treatment and a second exposure to 1% osmium. Walton’s lead aspartate exposure was not carried out, so preparation of the tissue was finished with a 1% uranyl acetate incubation followed by dehydration to propylene oxide, and the tissue was embedded in Durcupan ACM resin. The tissue was serially sectioned and imaged using the Gatan 3VIEW serial block-face imaging system (Gatan, Abingdon, UK) fitted to a Zeiss Sigma variable pressure-field emission scanning electron microscope (Zeiss, Cambridge, UK). Data was collected and used in Amira Software (FEI, Oregon, USA) in order to reconstruct the 3D images. Using the same software, photoreceptor mitochondrial volume was estimated for WT mice, around the lesion in Vldlr−/− mice, and away from the lesion in Vldlr−/− mice.

SWIFT_MACTEL. We created a set of macros that was developed to run on the ImageJ platform (NIH; http://imagej.nih.gov/ij/). In brief, SWIFT_MACTEL isolates the red channel from a lectin-stained retinal whole-mount, divides the image into four quadrants and removes background fluorescence to allow for the neovascularization (NV) structures to stand out clearly against the background fluorescence of normal vessels. Using a slide bar to either increase or decrease a particular quadrant’s fluorescence threshold, the SWIFT_MACTEL user designates a threshold that marks NV structures but not normal vessels in each quadrant. After setting the appropriate threshold, artifacts like cellular debris or hyperfluorescent retinal edges can be manually removed and excluded from quantification. SWIFT_MACTEL then analyzes all pixels in the image that lie above the chosen intensity threshold and that are part of an object that has a minimum size of 100 pixels. By setting this cut-off in object size, small artifacts like vessel branch points are automatically removed. After measuring all four quadrants, SWIFT_MACTEL creates a composite from all four NV quadrants and calculates the total NV pixel number. Results from the SWIFT_NV method have been found to correlate well with results from the established hand-measurement-based protocols (R2 = 0.9372) and show robust intra-individual (R2 = 0.9376) and inter-individual (R2 = 0.9424) reproducibility. The n number is the number of eyes quantified.

Glucose and lactate measurements. Whole retinas and photoreceptors (661W) were incubated in assay medium (DMEM 5030, 12 mM glucose, 10 mM HEPES) for 6 and 48 h, respectively. Medium was collected and spun briefly (13,000g) to remove cellular debris, and glucose and lactate levels measured using a Yellow Springs Instrument (YSI) 2950; results were compared to control medium that was not exposed to tissue or cells. To determine the conversion of glucose to lactate (the glycolytic rate), the amount of lactate produced was divided by the amount of glucose taken up.

Retinal lipid uptake. We compared retinal uptake of long-chain fatty acid in wild-type and Vldlr−/− mice gavaged with 0.1 mg of 4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-hexadecanoic acid (BODIPY FL C16; Molecular Probes). Mice were euthanized 2 h later, and the eyes were enucleated, embedded in OCT and cryosectioned (10 µm) for immediate imaging by fluorescence microscopy. Retinal fatty acid uptake was quantitated using a 14C-labeled 2-bromopalmitate tracer injected twice daily, i.p. (0.5 µg per dose) from P9 to P12; the total administered radioactivity was normalized for mouse body weight. Retinas were then dissected and homogenized in Ultima Gold liquid scintillation cocktail (PerkinElmer) and beta-counted (14C disintegration per minute or DPM) using a Tri-Carb 2900TR instrument (PerkinElmer), correcting for background scintillation.
Plasma triglycerides and fatty acid analysis. Plasma was isolated from WT and Vldlr<sup>−/−</sup> mice by centrifugation (200g × 20 min; 4 °C) of whole blood in EDTA-coated tubes. Triglycerides were determined using the Randox TRIGS kit (TR210), according to the manufacturer's instructions. Fatty acids in whole plasma were assayed as described previously<sup>45</sup>. Briefly, each sample was subjected to direct trans-esterification and then injected into a gas chromatograph using the Agilent GC AutoSampler system (7890A). Fatty acids were identified by comparison with the expected retention times of known standards and then analyzed with the OpenLAB Software Suite (Agilent).

β-oxidation metabolite quantification. Acylcarnitine metabolites were extracted from WT and Vldlr<sup>−/−</sup> (P12) flash-frozen retinas using ice-cold methanol. Samples were sonicated and centrifuged, and the supernatant was transferred to a fresh tube for nitrogen evaporation. After drying, butanolysis was performed (butanol-HCl, 55 °C for 20 min) before reconstitution in mobile phase (acetonitrile (ACN):H₂O 80:20, formic acid 0.05%). Samples were analyzed by liquid chromatography followed by tandem mass spectrometry (LC-MS/MS, Alliance 2795 LC and Quattro Micro, Waters Corp.). Data were recorded in positive-electrospray ionization mode and analyzed with Neolynx software (Waters Corp.).

Retinal glucose uptake. Positron emission tomography (PET) imaging studies were performed on WT, Vldlr<sup>−/−</sup>, Vldlr<sup>−/−</sup> Ffar1<sup>−/−</sup> and Ffar1<sup>−/−</sup> mice (P16; Focus 120 high-resolution; Siemens), followed by micro-computed axial tomography (microCAT) scan imaging (MicroCAT II scanner, Siemens). Fluorine-18 fluorodeoxyglucose ([<sup>18</sup>F]FDG) was administered by intraperitoneal injection to obtain nontoxic radioactivity levels (3.7 and 37 MBq; or 0.1 to 1.0 mCi). Actual administered activity was determined using a dose calibrator to measure activity in the syringe before and after the injection. Images were acquired 60 min after injection to ensure radiotracer uptake. Mice were fasted for 6 h before imaging, kept in darkness and anesthetized by inhalation of isoflurane (2–4%) through a nose cone for the duration of the procedure. Animals were imaged in a head first, prone position and placed on a heating pad to maintain appropriate body temperature. Upon completion of imaging, mice were euthanized and retinas were dissected for precise [<sup>18</sup>F]FDG retinal activity, quantification by gamma counter, and correction for decay. WT and Vldlr<sup>−/−</sup> mouse pups were also injected with trace amounts of 2-[^13]H]deoxyglucose (0.5 µCi daily, i.p.) and treated with GW9508 or vehicle (14 µM daily, i.p.) for 5 d (P7–P12). Retinas were collected and homogenized in a scintillation cocktail (Ecolite +; MP Biomedical), and beta counts were measured using a LS6500 Multipurpose Scintillation Counter (Beckman).

Immunoblots and enzyme-linked immunosorbent assay (ELISA). Retinal samples were obtained as described above. Retinal lysate (20 µg) from three different animals or endothelial cell lysate (10 µg) was loaded on an SDS-PAGE gel and electroblotted onto a polyvinylidene difluoride (PVDF) membrane (Bio-Rad). We used retinal nuclear extract (Abcam, Ab113474) to enrich Hif1α signals, according to the manufacturer's instructions. After blocking, the membranes were incubated with antibodies against β-actin (Sigma, A1978), fibrillin (Cell Signaling, 2639), Hif1α (Novus, NB100-134), and Glut1 (Novus, NB300-666 and Abcam, Ab652), Glut3 (Millipore, AB1344) and Glut4 (Abcam, ab654) overnight (1:1,000 each). After washing, membranes were incubated with 1:10,000 horseradish peroxidase–conjugated anti-rabbit or anti-mouse secondary antibodies (Amersham, NA931V and NA934V) for 1 h at room temperature. Densitometry was analyzed using ImageJ software (National Institutes of Health). The retina was visualized by ink dye and scanned with an Illumina BeadArray Reader to measure the signal intensity of the labeled target. Raw data were analyzed by microarray software (Bead Studio Gene Expression version 3.4.0) for quality control, background analysis and normalization with the rank-invariant algorithm. Normalized data was further analyzed for comparative molecular and cellular pathway regulation using Ingenuity Pathway Analysis (P = 0.05 and delta of 0.19; Qiagen)<sup>46</sup>.

Metabolite profiling. Metabolites of rapidly dissected WT and Vldlr<sup>−/−</sup> retinas (flash-frozen less than 1 min after euthanasia; 15 or 16 biological replicates) were homogenized in 80% methanol (8 µl/mg of tissue) containing the internal standards inosine[<sup>15</sup>N<sub>2</sub>], thymidine-d<sub>4</sub>, and glycolate-d<sub>4</sub> (Cambridge Isotope Laboratories) using a TissueLyser II (Qiagen) bead mill for 4 min at 20 Hz. Samples were centrifuged (9,000g, 10 min, 4 °C) to pellet debris, and supernatants were analyzed using two liquid chromatography tandem mass spectrometry (LC-MS/MS) methods to measure polar metabolites, as described previously<sup>47,48</sup>. Briefly, negative-ionization mode multiple-reaction mode (MRM) data were acquired using an ACQUITY UPLC instrument (Waters) coupled to a 5500 QTRAP triple-quadrupole mass spectrometer (AB SCIEX). The supernatants were injected directly onto a 150 × 2.0 mm Luna NH2 column (Phenomenex) that was eluted at a flow rate of 400 µl/min with initial conditions of 10% mobile phase A (20 µM ammonium acetate and 20 mM ammonium hydroxide (Sigma-Aldrich) in water (VWR)) and 90% mobile phase B (10 mM ammonium hydroxide in 75:25 vol/vol acetonitrile/methanol

Expression array. Illumina mouse gene-microarray analysis of WT and Vldlr<sup>−/−</sup> retinas was performed in biological triplicate (Mouse-WG6 expression BeadChip, Illumina). The chip contains 45,000 probe sets representing 34,000 genes. Microarray studies, from cDNA synthesis to raw data normalization, were performed by the Molecular Genetics Core Facility at Boston Children's Hospital. Briefly, total RNA (1 µg each) was reverse-transcribed, followed by a single in vitro transcription amplification to incorporate biotin-labeled nucleotide, and subsequent hybridization and staining with streptavidin-Cy3 was performed according to the manufacturer's instructions. The chip was scanned with an Illumina BeadArray Reader to measure the signal intensity of the labeled target. Raw data were analyzed by microarray software (Bead Studio Gene Expression version 3.4.0) for quality control, background analysis and normalization with the rank-invariant algorithm. Normalized data was further analyzed for comparative molecular and cellular pathway regulation using Ingenuity Pathway Analysis (P = 0.05 and delta of 0.19; Qiagen)<sup>46</sup>.
(VWR)) followed by a 10 min linear gradient to 100% mobile phase A. The ion spray voltage was −4.5 kV, and the source temperature was 500 °C. Positive-ionization mode MRM data were acquired using a 4000 QTRAP triple-quadrupole mass spectrometer (AB SCIEX) coupled to an 1100 Series pump (Agilent) and an HTS PAL autosampler (Leap Technologies). Cell extracts (10 µl) were diluted using 40 µl of 74.9:24.9:9.0 (vol/vol/vol) acetonitrile/methanol/formic acid containing stable isotope-labeled internal standards (0.2 ng/µl valine-d8, Isotec; and 0.2 ng/µl phenylalanine-d8 (Cambridge Isotope Laboratories) and were injected onto a 150 × 2.1 mm Atlantis HILIC column (Waters). The column was eluted isocratically at a flow rate of 250 µl/min with 5% mobile phase A (10 mM ammonium formate and 0.1% formic acid in water) for 1 min followed by a linear gradient to 40% mobile phase B (acetonitrile with 0.1% formic acid) over the course of 10 min. The ion spray voltage was 4.5 kV, and the source temperature was 450 °C. Raw data were processed using MultiQuant 2.1 (AB SCIEX) for automated peak integration, and metabolite peaks were manually reviewed for quality of integration and compared against known standards to confirm identity.

**Photoreceptor (661W) cell culture.** Cone photoreceptor cells49,50 were cultured as monolayers at 37 °C, 5% CO2 in a humidified atmosphere in DMEM with FBS 10% supplemented with hydrocortisone (20 µg/500 µl; H-2270, Sigma), progesterone (20 µg/500 µl; P-8783, Sigma), putrescine (0.016 g/500 ml; P-7505, Sigma) and β-mercaptoethanol (20 µl/500 ml; M-6250, Sigma). No mycoplasma contamination of the cells was detected. An equal number of 661W cells (0.3 × 10⁶) was plated in each well of 6-well dishes and cultured to 80% confluence. Cells were washed twice with PBS, starved for 4 h (in the above-mentioned medium without FBS) and then stimulated with GW9508 (14 µM, Cayman) or vehicle. Photoreceptors were collected 8 h after treatment to determine Hif1a protein expression by immunoblotting, and conditioned medium was collected at 12 h to quantify Vegfa levels by ELISA (MMV00, R&D Systems) according to the manufacturer’s instructions. Vegfa concentrations were normalized for the number of cells per well by measuring the total cellular protein content of each sample, as assessed by the BCA assay.

**Preparation of AAV2-RK-shVldlr vector and AAV2 virus.** Three shRNAs, each of which targets all eight variants of mouse Vldlr, were designed using a published algorithm51. DNA fragments were amplified, purified, digested and inserted into a modified CAG-GFP-miR30 vector according to a previous report52; the synthetic CAG promoter (which includes the cytomegalovirus early enhancer element, the chicken β-actin promoter and the splice acceptor of the rabbit beta globin gene) was replaced with the promoter of the gene encoding rhodopsin kinase (RK; encoded by GRIK1) that was isolated from a pAAV-RK-GFP vector53. Vldlr knockdown efficiency was tested in retinas from P0 C57BL/6 pups. Recombinant AAV2 vectors were produced as previously described54. Briefly, the AAV vector, the replication-capid carrying plasmid, and adenoviral helper plasmid were mixed with polyethyleneimine and transfected into HEK293T cells (CRL-11268, American Type Culture Collection). Seventy-two hours after transfection, cells were harvested and the cell pellet was resuspended in virus buffer, followed by three cycles of freeze-thawing, and then homogenization. Cell debris was pelleted at 5,000g for 20 min, and the supernatant was run on an iodixanol gradient. Recovered AAV vectors were washed three times with PBS using Amicon 100K columns (EMD Millipore). Real-time PCR was used to determine genome titers of the recombinant AAV. This protocol was also used to prepare a control AAV2-shControl. Virus concentration of approximately 2 × 10¹² genome copies per ml (gc/ml) was used for the experiments. The sequences (5′-3′) of the mouse Vldlr-specific siRNAs were as follows: shVldlr #1, GGAAGTCTCAAGTGCAGAAGCG; shVldlr #2, GGAATGCCATATCAGCAAGTGC; shVldlr #3, GGGATCTCGACGACTCAATT GTGA; Scramble shRNA control, GATTGAAGCAGCGTATACA.

**Human samples and vitrectomy.** The study conforms to the tenets of the Declaration of Helsinki, and approval of the human clinical protocol and informed consent were obtained from the Maisonneuve-Rosemont Hospital (HMR) ethics committee (ref. CER: 10059). All patients previously diagnosed with AMD or macular hole (without neovascularization, but requiring vitrectomy for treatment) were followed clinically, and surgery was performed, when indicated by ‘standard-of-care’ guidelines, by a single vitreoretinal surgeon (F.A.R.). Vitreous samples were frozen on dry ice immediately after biopsy and stored at −80°C. VEGFA ELISAs were performed according to manufacturer’s instructions (DVE00, R&D Systems).

**Statistical analysis.** We used Student’s t-test, and ANOVA with Dunnet, Bonferroni or Tukey post hoc analysis (see Supplementary Table 2) to compare different groups; P < 0.05 was considered as statistically significant. The D’Agostino-Pearson or Kolmogorov-Smirnov (KS) normality test was used to confirm a normal distribution. Data with non-Gaussian distribution was analyzed was analyzed using a Mann Whitney U test (nonparametric, two groups). Animals were not randomized, but quantification of the data was performed in a blinded fashion when possible. All experiments were repeated at least three times. Values ± s.d. from the mean were considered to be outliers and were excluded. Sample size was estimated to detect a difference of 20% with a power of 80% (1 − β) and an α of 0.05. Results are presented as mean ± s.e.m.

Nat. Med.; doi:10.1038/nm.4059; corrected 24 March 2016

In the version of this article initially published online, there were two errors. There was a typographical error in the text, which should have stated that the ‘dark current’ is an electrochemical gradient required for photon-induced polarization (rather than depolarization, as incorrectly stated). In addition, some funding sources were inadvertently omitted from the Acknowledgments. The errors have been corrected for the print, PDF and HTML versions of this article.

Corrigendum: ROR-γ drives androgen receptor expression and represents a therapeutic target in castration-resistant prostate cancer

Nat. Med.; doi:10.1038/nm.4070; corrected online 22 April 2016

In Figure 2a of the version of this article initially published online, one phenyl ring was inadvertently deleted from the chemical structure of compound SR2211. One affiliation of H.-W.C. (Veterans Affairs Northern California Health Care System–Mather, Mather, California, USA) was also inadvertently omitted. These errors have been corrected for the print, PDF and HTML versions of this article.

Corrigendum: Protection against malaria at 1 year and immune correlates following PfSPZ vaccination
