Abstract. We present a new model for the global tropospheric chemistry of inorganic bromine (Brₓ) coupled to oxidant-aerosol chemistry in the GEOS-Chem chemical transport model (CTM). Sources of tropospheric Brₓ include debromination of sea-salt aerosol, photolysis and oxidation of short-lived bromocarbons, and transport from the stratosphere. Comparison to a GOME-2 satellite climatology of tropospheric BrO columns shows that the model can reproduce the observed increase of BrO with latitude, the northern mid-latitudes maximum in winter, and the Arctic maximum in spring. This successful simulation is contingent on the HOBr + HBr reaction taking place in aqueous aerosols and ice clouds. Bromine chemistry in the model decreases tropospheric ozone mixing ratios by < 1–8 nmol mol⁻¹ (6.5 % globally), with the largest effects in the northern extratropics in spring. The global mean tropospheric OH concentration decreases by 4 %. Inclusion of bromine chemistry improves the ability of global models (GEOS-Chem and p-TOMCAT) to simulate observed 19th-century ozone and its seasonality. Bromine effects on tropospheric ozone are comparable in the present-day and pre-industrial atmospheres so that estimates of anthropogenic radiative forcing are minimally affected. Br atom concentrations are 40 % higher in the pre-industrial atmosphere due to lower ozone, which would decrease by a factor of 2 the atmospheric lifetime of elemental mercury against oxidation by Br. This suggests that historical anthropogenic mercury emissions may have mostly deposited to northern mid-latitudes, enriching the corresponding surface reservoirs. The persistent rise in background surface ozone at northern mid-latitudes during the past decades could possibly contribute to the observations of elevated mercury in subsurface waters of the North Atlantic.

1 Introduction

Bromine radicals (BrOₓ ≡ Br + BrO) are well-known catalysts for ozone destruction in the stratosphere (Clerbaux et al., 2007), and also drive ozone depletion and mercury oxidation in polar surface air (Simpson et al., 2007; Steffen et al., 2008). In the stratosphere, bromine radicals originate from photolysis and oxidation of halons and shorter-lived bromocarbons (Clerbaux et al., 2007; Law et al., 2007). In polar surface air, they originate from photochemistry involving sea salt in aerosol or on sea ice (Simpson et al., 2007; Yang et al., 2008). There is growing evidence that bromine radical chemistry could be important in the background troposphere as well, with remote sensing observations typically
reporting 0.5–2 pmol mol\(^{-1}\) BrO (Harder et al., 1998; Frieß et al., 1999; Fitzenberger et al., 2000; Van Roozendael et al., 2002; Richter et al., 2002; Platt and Hönninger, 2003; Hendrick et al., 2007; Theys et al., 2007, 2011) and aircraft observations reporting several pmol mol\(^{-1}\) BrO in the free troposphere (Neuman et al., 2010; Salawitch et al., 2010). Chemical transport model (CTM) studies show that \(~\sim 1\) pmol mol\(^{-1}\) BrO in the background troposphere would drive significant decrease of ozone (von Glasow et al., 2004; Lary, 2005; Yang et al., 2005) and could account for most of the global oxidation of elemental mercury (Holmes et al., 2006, 2010).

Bromine radical chemistry in the troposphere is initiated by the production of gas-phase inorganic bromine ($Br_y$) from photolysis and oxidation of short-lived bromocarbons and from debromination of sea-salt aerosol (Yang et al., 2005; Kerkweg et al., 2008). $Br_y$ cycles between BrO and non-radical reservoirs (principally HBr, HOBr, BrNO\(_3\), BrNO\(_2\), Br\(_2\)) and is eventually lost by deposition. Sea salt aerosol debromination represents the largest source of $Br_y$ to the troposphere, with estimates between 1000 and 6000 Gg Br a\(^{-1}\) constrained by the observed Br depletion in sea-salt aerosol relative to seawater composition (Sander et al., 2003). This source is mainly in the marine boundary layer where $Br_y$ has a short lifetime against deposition. Bromocarbons emitted by the marine biosphere including CHBr\(_3\), CH\(_2\)Br\(_2\), and CH\(_3\)Br can release $Br_y$ in the free troposphere where its lifetime against deposition is much longer. Global emission estimates are in the range 370–1400 Gg Br a\(^{-1}\) for CHBr\(_3\) and 57–280 Gg Br a\(^{-1}\) for CH\(_2\)Br\(_2\) (Quack and Wallace, 2003; Warwick et al., 2006; Law et al., 2007; Liang et al., 2010; Pyle et al., 2011). CH\(_3\)Br also has a large anthropogenic source as an agricultural pesticide (Clerbaux et al., 2007) and its contribution to tropospheric $Br_y$ production has been estimated at 60–80 Gg Br a\(^{-1}\) (Yvon-Lewis et al., 2009). Implementation of these sources in the p-TOMCAT CTM together with relatively well-established gas-phase $Br_y$ chemistry yields a background tropospheric BrO mixing ratio of \(~\sim 0.5\) pmol mol\(^{-1}\), at the low end of observations (Yang et al., 2005).

Here we incorporate a detailed simulation capability for tropospheric bromine coupled to oxidant-aerosol chemistry in the GEOS-Chem CTM (Bey et al., 2001). We evaluate this simulation with a recent space-based climatology of tropospheric BrO in the GEOS-5 assimilated meteorological fields for the present-day and pre-industrial atmospheres. Several studies have pointed out the inability of current CTMs to reproduce the low surface ozone observations from the turn of the 20th century, suggesting that CTM-based estimates of the anthropogenic radiative forcing from tropospheric ozone are too low (Wang and Jacob, 1998; Kiel et al., 1999; Mickley et al., 2001; Shindell et al., 2003; Lamarque et al., 2005; Horowitz, 2006). As we will show, inclusion of bromine chemistry helps to correct this apparent model deficiency.

### 2 GEOS-Chem bromine simulation

The GEOS-Chem CTM (http://www.geos-chem.org) has been used extensively for studies of global oxidant-aerosol chemistry. A recent description of the model radical chemistry is given in Mao et al. (2010), and a recent evaluation of the global tropospheric ozone simulation with sonde and satellite observations is given in Zhang et al. (2010). We developed a tropospheric bromine simulation capability fully coupled to the standard oxidant-aerosol chemistry mechanism in version 8-02-02 of the model. The simulation includes ten bromine species transported in the model: Br\(_2\), Br, BrO, HBr, HOBr, BrNO\(_3\), BrNO\(_2\), CHBr\(_3\), CH\(_2\)Br\(_2\), and CH\(_3\)Br. Here we describe the relevant emissions, chemistry, and deposition. All GEOS-Chem simulations presented here have horizontal resolution of 4° latitude × 5° longitude, 47 vertical layers extending from the surface to ~80 km in altitude, and an external chemical time step of 1 h. Transport is driven by GEOS-5 assimilated meteorological fields for 2007 from the NASA Global Modeling and Assimilation Office (GMAO). The chemical mechanism is integrated with the SMVGEAR solver for all tropospheric gridboxes (Jacobson and Turco, 1994; Bey et al., 2001). Linear chemistry with climatological rates is used for the stratosphere (Bey et al., 2001), including improved treatment of ozone chemistry with the Linoz parameterization (McLinden et al., 2000). Stratospheric $Br_y$ concentrations are specified from a model climatology as described below.

### 2.1 Tropospheric sources of $Br_y$

Tropospheric $Br_y$ is produced in the model by debromination of sea salt aerosol (SSA), photolysis of CHBr\(_3\), and oxidation of CHBr\(_3\), CH\(_2\)Br\(_2\), and CH\(_3\)Br by OH (Table 1). SSA observations indicate typically a 50% loss of bromide ($Br^-\$) relative to seawater composition, implying release to the atmosphere as $Br_y$ (Sander et al., 2003). This release may take place by a set of complicated multiphase reactions producing Br\(_2\), BrCl, or HOBr (Vogt et al., 1996; Sander et al., 1999, 2003), all of which rapidly photolyze to release BrO\(_x\) radicals. Our simplified treatment of SSA debromination follows

| Source                          | Emission, Gg Br a\(^{-1}\) | Lifetime, d* |
|---------------------------------|-----------------------------|--------------|
| Sea salt debromination          | 1420                        | ~0           |
| CHBr\(_3\)                     | 407                         | 21           |
| CH\(_2\)Br\(_2\)               | 57                          | 91           |
| CH\(_3\)Br                     | 56                          | 402          |
| Transport from stratosphere     | 36                          | ~0           |

*Global mean tropospheric lifetimes of bromocarbons determining the release of $Br_y$. Values of ~0 are entered for the sea salt debromination and stratospheric sources because these sources are as $Br_x$.

* The Arrhenius expression for rate constants is \( k = A \exp(-E_a/RT) \). Kinetic data are from Sander et al. (2011) except for Reactions (R7) (Atkinson et al., 2000), (R8) (King et al., 1970), (R9) and (R10) (Seakins et al., 1992), and (R11) (Orlando and Tyndall, 1996).

...
than in the tropics, reflecting the differences in lifetimes. The model reproduces well these observations.

Figure 2 compares seasonal tropospheric columns of CHBr3 and CH2Br2 in the tropics and northern extratropics for the ensemble of NASA aircraft campaigns. This provides a test of emissions in the model. We find that the aseasonal emissions of CHBr3 from Liang et al. (2010) overestimate CHBr3 columns in the northern extratropics during winter and spring, and therefore we apply a seasonal correction factor to these emissions as shown in the figure. No systematic bias is otherwise apparent for CHBr3 in the tropics or for CH2Br2. Our global CHBr3 source is 407 Gg Br a−1 globally (compared to 425 Gg Br a−1 in Liang et al., 2010). Pyle et al. (2011) recently estimated a global CHBr3 source of 380 Gg Br a−1 constrained with observations from the OP3 campaign over the maritime continent. Our global CH2Br2 source is 57 Gg Br a−1, same as Liang et al. (2010).

CH3Br has a sufficiently long lifetime to be well-mixed in the troposphere. Surface air observations from the NOAA/GMD global network show a near-uniform mixing ratio of 6–9 pmol mol−1 (Montzka et al., 2003) and we use these as lower boundary condition in the model: 6.7 pmol mol−1 in the Southern Hemisphere and 8.5 pmol mol−1 in the Northern Hemisphere. The implied tropospheric source of Brx to balance the computed CH2Br sink in GEOS-Chem is 56 Gg Br a−1, slightly lower than a previous estimate of 63–78 Gg Br a−1 (Saltzman et al., 2004).

Halons and other bromocarbons photolyzed or oxidized in the stratosphere represent an additional source of Brx to the troposphere. This is treated here as an upper boundary condition above the local model tropopause using archived Brx concentrations from the Liang et al. (2010) stratospheric simulation with the GEOS-5 CCM. The mean stratospheric Brx mixing ratio in that simulation is 22 pmol mol−1. We use monthly mean 3-D concentration data from Liang et al. (2010) for individual Brx species, separately for daytime and nighttime. The resulting cross-tropopause source of tropospheric Brx in GEOS-Chem is 36 Gg Br a−1, as determined by difference with a sensitivity simulation using a zero-concentration upper boundary condition for all Brx species above the tropopause.

Table 2b. Tropospheric bromine chemistry in GEOS-Chem: three-body reactions^a.

| Reaction number | Reaction | Rate coefficients^b |
|-----------------|----------|---------------------|
| R20             | Br + NO2 + M → BrNO2 + M | $k_0 = 4.2 \times 10^{-31} (T/300)^{-2.4}, k_\infty = 2.7 \times 10^{-11}, F_c = 0.6$ |
| R21             | BrO + NO2 + M → BrNO3 + M | $k_0 = 5.2 \times 10^{-31} (T/300)^{-3.2}, k_\infty = 6.9 \times 10^{-12}, F_c = 0.6$ |

^a The rate constant is calculated as $k = [k_0(M)/(1 + k_0(M)/k_\infty)] \times F_0^n$, where $n = 1 + (\log_{10}(k_0(M)/k_\infty))^2$ and [M] is the air number density (molecules cm−3).

^b from Sander et al. (2011); $k_0$ and $k_\infty$ have units of cm6 molecule−2 s−1 and cm3 molecule−1 s−1 respectively, and $T$ has units of K.

Table 2c. Tropospheric bromine chemistry in GEOS-Chem: three-body reactions^a.

| Reaction number | Reaction | $J_s$ s−1 b |
|-----------------|----------|-------------|
| R22             | CHBr3 $+$ hν $\rightarrow$ 3Br + products | $1.1 \times 10^{-6}$ |
| R23             | Br2 $+$ hν $\rightarrow$ 2Br | $4.2 \times 10^{-2}$ |
| R24             | BrO $+$ hν $\rightarrow$ Br + O3 | $4.0 \times 10^{-2}$ |
| R25             | HOBr $+$ hν $\rightarrow$ Br + OH | $2.3 \times 10^{-3}$ |
| R26             | BrNO2 $+$ hν $\rightarrow$ Br + NO2 | $1.2 \times 10^{-3}$ |
| R27             | BrNO3 $+$ hν $\rightarrow$ BrO + NO2 | $2.2 \times 10^{-4}$ |
| R28             | BrNO3 $+$ hν $\rightarrow$ Br + NO3 | $1.2 \times 10^{-3}$ |

^a photolysis rates are calculated locally with the Fast-J radiative transfer model (Wild et al., 2000) using absorption cross-sections from Sander et al. (2011) except for Reaction (R26) (Scheffler et al., 1997). All quantum yields are assumed to be 100 % (Sander et al., 2011).

^b global annual tropospheric mean photolysis frequencies calculated in GEOS-Chem.

Fig. 1. Mean vertical profiles of CHBr3 and CH2Br2 concentrations in the northern extratropics (latitudes > 30° N) and tropics (30° S–30° N) for April–June. GEOS-Chem model results (in red) are compared to observations from NASA aircraft campaigns (in black) including TRACE-P, INTEX-B, and ARCTAS. See Liang et al. (2010) for references on the aircraft observations. Vertical profiles have been averaged over coherent regions for individual missions and then averaged again over the latitudinal domain. Horizontal bars are standard deviations in the original data.
Table 2d. Tropospheric bromine chemistry in GEOS-Chem: heterogeneous processes.

| Reaction number | Reaction                               | Reactive uptake probability ($\gamma^a$) |
|-----------------|----------------------------------------|------------------------------------------|
| R29             | BrNO$_3$ $\rightarrow$ HBrO$_2$(aerosol, cloud) | 0.3 (sea salt, liquid cloud)$^{b}$, 0.8 (sulfate)$^{c}$ |
| R30             | HOBr + HBr $\rightarrow$ Br$_2$ + H$_2$O   | 0.2 (sea salt, sulfate), 0.1 (ice)$^{f}$   |

$^a$ See Eq. (1) in text; $^b$ IUPAC evaluation (Atkinson et al., 2000b); $^c$ Sander et al. (2011); for Reaction (R30) the reactive uptake probability is applied to the limiting reactant.

Figure 2. Comparison of simulated (red) and observed (black) tropospheric columns (molecules cm$^{-2}$) of CH$_2$Br$_2$ and CHBr$_3$, for the northern extratropics (> 30°N) and the tropics (30°S–30°N).

Table 2e. Tropospheric bromine chemistry in GEOS-Chem: Henry’s law constants.$^a$

| Species        | $K_H$ (298), M atm$^{-1}$ | $\Delta H/R$, K | Reference          |
|----------------|--------------------------|-----------------|--------------------|
| HBr            | 0.75 (7.5 $\times$ 10$^{13}$) | 10200           | Schweitzer et al. (2000) |
| HOBr           | 6100$^c$                 | 6010$^d$        | Frenzel et al. (1998) |
| Br$_2$         | 0.76                     | 4180            | Dean (1992)         |
| Br             | 1.2                      | 1800            | Sander (1999)       |
| BrO$^f$        | 0.71                     |                 | Frenzel et al. (1998) |
| BrNO$_2$       | 0.3                      |                 | Frenzel et al. (1998) |
| BrNO$_3$       | $\infty$                 |                 | Sander (1999)       |

$^a$ The Henry’s law constant is calculated as $K_H(T) = K_H(298) \exp \left( -\frac{\Delta H}{R} \left( \frac{1}{T} - \frac{1}{298} \right) \right)$, where $K_H(298)$ is the value at 298 K, $\Delta H$ is the enthalpy of solution, $R$ is the gas constant, and $T$ is the temperature (K).

$^b$ The Henry’s Law constant is from Schweitzer et al. (2000); The value in parentheses is the effective Henry’s law constant $K_{H_{eff}}$ at pH 5 accounting for HBr(aq)/Br$^-$ dissociation: $K_{H_{eff}} = K_H(T) \left( 1 + k_{H_2O} \right)$, where $K_H(T) = K_H(298) \exp \left( -\frac{\Delta H}{R} \left( \frac{1}{T} - \frac{1}{298} \right) \right)$.

$^c$ HOBr(aq)/BrO$^-$ acid dissociation is negligible under atmospheric conditions ($K_a = 1.6 \times 10^{-9}$ M, Haag and Hoigne, 1983).

$^d$ McGrath and Rowland (1994)

$^e$ Br$_2$(aq) dissociation by hydrolysis can be neglected (Beckwith et al., 1996).

$^f$ Estimated by analogy with ClO (Sander et al., 2011).

$^g$ BrNO$_3$ uptake by liquid clouds is modeled by a reactive uptake probability (Table 2d) and is not limited by Henry’s law solubility. For modeling dry deposition an infinite Henry’s law constant is assumed.

2.2 Chemical cycling of Br$_y$

Other tropospheric Br$_y$ sources are neglected as unimportant on a global scale. Kerkweg et al. (2008) estimated that photo-oxidation of bromocarbons other than CHBr$_3$, CH$_2$Br$_2$, and CH$_3$Br accounts for 24 Gg Br a$^{-1}$ of tropospheric Br$_y$. Pyle and Mather (2009) estimated a global volcanic source of 5–15 Gg Br a$^{-1}$. Photolysis rates are calculated online with the Fast-J radiative transfer model (Wild et al., 2000). Heterogeneous bromine chemistry in aqueous aerosols includes hydrolysis of BrNO$_3$ (Reaction R29) and reaction between HOBr and HBr (Reaction R30). Both are treated with a standard reactive uptake probability ($\gamma$) formulation, resulting in an effective gas-phase loss rate constant to a monodisperse aerosol (radius $a$) given by

$$k = \left( \frac{a}{D} + \frac{4}{\nu \gamma} \right)^{-1} A$$

Here $D$ is the molecular diffusion coefficient in air, $\nu$ is the mean molecular speed of the gas, and $A$ is the aerosol surface area concentration per unit volume of air (cm$^2$ cm$^{-3}$) (Schwartz, 1986; Jacob, 2000). GEOS-Chem simulates explicitly the mass concentrations of different aerosol types, and we integrate $k$ over the prescribed relative humidity-dependent size distributions as described by
Martin et al. (2002). Reactive uptake probabilities for both Reactions (R29) and (R30) are based on existing laboratory evidence (Table 2d) but with limited information on the sensitivity to temperature and aerosol composition. For BrNO3 hydrolysis Reaction (R29) on liquid cloud droplets, the cloud surface area concentration A is calculated from GEOS-5 liquid water content data, assuming effective droplet radii of 10 μm and 6 μm for marine and continental clouds respectively (Park et al., 2004; Fu et al., 2008). For HBr + HOBr (Reaction R30) on ice cloud surfaces, we use \( A = 2 \times 10^{-4} \) cm\(^{-2}\) (Lawrence and Crutzen, 1998) applied to the local ice water content \( I \) (cm\(^3\) cm\(^{-3}\)) from the GEOS-5 data.

Reaction (R30) is an important pathway for recycling bromine radicals in the troposphere (von Glasow et al., 2004; Yang et al., 2010). Although the kinetics are uncertain, there is substantial evidence for this reaction. Abbott (1995) measured \( \gamma > 0.25 \) for HBr + HOBr in sulfuric acid solution (69 wt %) with HBr present in excess. Laboratory measurements show that HOBr reactive uptake on deliquescent NaBr and NaCl aerosol has \( \gamma > 0.2 \) for pH < 7 (Abbatt and Waschewsky, 1998; Fickert et al., 1999; Wachsmuth et al., 2002). Fickert et al. (1999) determined the relative production of Br\(_2\) vs. BrCl for HBr reacting with aqueous salt solutions containing both Br\(^{-}\) and Cl\(^{-}\), and found \( \geq 90\%\) Br\(_2\)(g) production for [Br\(^{-}\)]/[Cl\(^{-}\)] ratios typical of seawater. Mochida et al. (1998) measured \( \gamma = 0.18 \pm 0.02 \) for HOBr reactive uptake on solid KBr. On ice surfaces with excess HBr, Abbott (1994) measured \( \gamma = 0.12 \pm 0.03 \) for HOBr + HBr at 228 K, and Chaix et al. (2000) measured \( \gamma = 0.15 \pm 0.03 \) at 205 K. Based on this ensemble of evidence and the recommendation of Sander et al. (2011), we assume that Reaction (R30) proceeds with \( \gamma = 0.2 \) for sulfate and sea salt aerosol (presumed aqueous) and \( \gamma = 0.1 \) for ice surfaces, where \( \gamma \) is applied to the locally limiting reactant. This simplified approach assumes that the non-limiting gas is at equilibrium with the aerosol phase.

### 2.3 Sinks of Br\(_y\)

Individual Br\(_y\) species are removed by wet and dry deposition. Wet deposition in GEOS-Chem takes place by scavenging in convective updrafts and by in- and below-cloud scavenging from large-scale and convective precipitation (Liu et al., 2001). A standard test for wet deposition in global CTMs is simulation of \(^{210}\)Pb aerosol, for which the source and atmospheric concentrations are relatively well constrained (Balkanski et al., 1993). Our version of GEOS-Chem yields a tropospheric lifetime of \(^{210}\)Pb against deposition of 9.5 days (L. T. Murray, personal communication, 2011), consistent with a best observational estimate of 9 days (Liu et al., 2001).

Different gas scavenging efficiencies are used in GEOS-Chem for warm liquid clouds (\( T > 268 \) K), mixed clouds (248 < \( T < 268 \) K), and cold ice clouds (\( T < 248 \) K). For warm clouds, partitioning into the aqueous phase is determined by the Henry’s law constant (Table 2e) and the liquid volume fraction of the precipitating water. Precipitation in mixed clouds is assumed to take place by riming, and the scavenging efficiency depends on the retention efficiency when the cloud droplets freeze (Stuart and Jacobson, 2003). For HBr we assume a 100% riming retention efficiency, following recommendations from Stuart and Jacobson (2003) for gases with large effective Henry’s Law constants. For other Br\(_y\) species we assume no retention during riming. We find little sensitivity to the assumed retention efficiency, consistent with previous GEOS-Chem studies for scavenging of ammonia (Wang et al., 2008; Fisher et al., 2010). We assume no scavenging from cold clouds. HBr and HOBr undergo heterogeneous chemistry at the surface of ice particles as discussed in Sect. 2.2.

Dry deposition velocities are calculated locally in GEOS-Chem following a standard resistance-in-series model with surface resistance determined by the Henry’s law constant, surface type, and meteorological conditions (Wesely, 1989; Wang et al., 1998). The resulting global annual mean deposition velocities are 0.94 cm s\(^{-1}\) for BrNO\(_3\), 0.93 cm s\(^{-1}\) for HBr, and 0.40 cm s\(^{-1}\) for HOBr.

### 3 Global budget of tropospheric Br\(_y\)

Figure 3 shows the global annual mean budget and cycling of tropospheric Br\(_y\) in our simulation. The BrO mixing ratio is 0.32 pmol mol\(^{-1}\), which implies a daytime mean of 0.64 pmol mol\(^{-1}\) since nighttime concentrations are near zero. This is at the low end of the oft-cited (but poorly constrained) 0.5−2 pmol mol\(^{-1}\) range in the observations; more detailed comparison with satellite observations will be presented in Sect. 4, and comparison against BrO observations taken at Cape Verde will be presented by Stone and Evans (2012). The global mean Br\(_y\) mixing ratio is 3.2 pmol mol\(^{-1}\), with HBr and HOBr as the principal reservoirs accounting respectively for 34% and 28% of total Br\(_y\). Br\(_y\) has a lifetime of 7 days against deposition, with HBr accounting for 55% of that sink and HOBr for 40%. Chemical lifetimes are short relative to deposition; that of HBr (the longest-lived reservoir) is only 6 h. Thus the BrO\(_x\) radical concentrations are effectively maintained by chemical recycling from non-radical reservoirs.

We see from Fig. 3 that the HBr+HOBr heterogeneous Reaction (R30) plays an important role in the recycling of Br\(_x\) from HBr. A sensitivity simulation without this reaction indicates a factor of 2 decrease in the BrO mixing ratio to 0.15 pmol mol\(^{-1}\), with HBr accounting for 70% of Br\(_y\); the lifetime of Br\(_y\) is shorter in that simulation (5 days) because of the high water solubility of HBr (Table 2e). The importance of Reaction (R30) reflects the comparable concentrations of HBr and HOBr (Fig. 3), as rapid HOBr production by the BrO + HO\(_2\) Reaction (R18) compensates for the much longer lifetime of HBr (6 h) than HOBr (20 min).
Figure 3. Global annual mean budget of tropospheric inorganic bromine (Br$_y$) in GEOS-Chem. The main reactions are indicated. Inventories are given as masses (Gg Br), with mixing ratios (pmol mol$^{-1}$) in brackets. Rates are given in units of Gg Br s$^{-1}$. Read 6.3(−5) as 6.3 × 10$^{-5}$. HBr accounts for 55% of Br$_y$ loss by deposition. Sea-salt aerosol debromination is the dominant global source of Br$_y$ but is mainly confined to the marine boundary layer where Br$_y$ has a short lifetime against deposition. It accounts for 48% of the Br$_y$ source in the global free troposphere.

Figure 4 shows the zonal annual mean BrO, Br, and Br$_y$ mixing ratios in the model. The highest concentrations of Br$_y$ and BrO are in the marine boundary layer at southern mid-latitudes due to the large source from sea-salt aerosol debromination. In the rest of the troposphere Br$_y$ is relatively uniform (2–4 pmol mol$^{-1}$), with a minimum in the tropical upper troposphere due to scavenging in convective updrafts. Mixing ratios increase with altitude in the stratosphere where the boundary conditions from Liang et al. (2010) are applied.

BrO and Br concentrations in Fig. 4 show a general increase with altitude, and BrO shows in addition an increase with latitude. The budget of BrO is largely that of BrO$_x$ since [BrO] ≫ [Br]. From Fig. 3 we see that the dominant sink of BrO$_x$ is the BrO + HO$_2$ Reaction (R18), which is fastest in the tropical lower troposphere where HO$_2$ concentrations are highest. The dominant source of Br is photolysis of BrO (Fig. 3), which cancels the latitudinal dependence of BrO concentrations and drives the strong increase of Br concentrations with altitude.

4 Comparison to satellite observations of tropospheric BrO

Figure 5 compares simulated BrO tropospheric columns to a GOME-2 satellite data set retrieved by Theys et al. (2011) with monthly resolution for 2007 and for six latitudinal bands. Theys et al. (2011) fitted total slant columns of BrO to the solar backscattered radiation spectra. They then removed the stratospheric contribution by using correlations of stratospheric BrO with ozone and NO$_2$ from the BASCOE 3D-CTM (Theys et al., 2009) and applying these correlations to the local GOME-2 observations of ozone and stratospheric NO$_2$ columns. They converted the tropospheric slant columns to vertical columns with an air mass factor assuming a Gaussian-shaped vertical distribution of BrO peaking at 6 km altitude. The grey shading in Fig. 5 indicates the total observational error estimated by Theys et al. (2011), including contributions from the air mass factor, surface albedo, cloud fractions, stratospheric BrO column removal, and cloud top heights.

The GOME-2 data are for ~09:30 local time (LT) and we sample GEOS-Chem at 09:00–11:00 LT for comparison. GEOS-Chem data in Fig. 5 include both the actual tropospheric vertical columns (red) and the columns corrected for the Theys et al. (2011) air mass factors using their tabulated scattering weights including for partly cloudy scenes. The correction is uncertain because the tabulation of scattering
weights is sparse, but the effect is relatively small except at southern mid-latitudes where the model BrO has a large contribution from the boundary layer. Also shown in Fig. 5 are actual tropospheric vertical columns sampled at 09:00–11:00 LT from the p-TOMCAT CTM bromine simulation of Yang et al. (2010), (blue) and from GEOS-Chem without the HBr + HOBr Reaction (R30) (dashed). p-TOMCAT and GEOS-Chem have completely different heritages. Specific differences in the p-TOMCAT simulation of bromine include the use of a smaller rate constant for HBr + HOBr ($\gamma = 0.02$ instead of 0.2, and no reaction on cloud ice particles), and consideration of a blowing snow source in polar regions during spring.

The standard GEOS-Chem simulation underestimates the GOME-2 observations by 30 % on a global mean basis, excluding the poles (40 % including the air mass factor correction). This is marginally significant considering the observation error but might indicate a low bias in the simulated emissions or heterogeneous recycling of Br$_2$. The observations show a positive BrO gradient with increasing latitude that is well reproduced in GEOS-Chem contingent on the (Reaction R30) HBr + HOBr reaction. Although Reaction (R30) is a photochemical pathway inasmuch as HOBr and HBr are mainly produced photochemically, it is most effective when radiation is weak since aerosol uptake of HOBr competes with HOBr photolysis. Thus the effect of Reaction (R30) for BrO$_2$ recycling is relatively small in the tropics but very large in the extratropics. It has a strong effect on seasonality in the extratropics, enabling GEOS-Chem to reproduce the observed winter maximum at northern mid-latitudes, in contrast to p-TOMCAT where Reaction (R30) is less important due to a seasonally constant non-sea salt aerosol loading and lower $\gamma$.

We conducted several sensitivity simulations to examine if uncertainties in gas-phase bromine kinetics as estimated by Sander et al. (2011) could account for the 30 % global model underestimate of BrO relative to the Theys et al. (2011) data. We found the effects to be relatively small. The largest response was from the Br + CH$_2$O Reaction (R5). Decreasing the pre-exponential factor for that reaction by 30 % and increasing the activation energy by 30 % (error standard deviations from Sander et al., 2011) resulted in a 19 % global increase in simulated BrO.

A major feature in the BrO observations of Theys et al. (2011) is the strong Arctic spring maximum. This is reproduced by both GEOS-Chem and p-TOMCAT but for different reasons. In GEOS-Chem it is due mainly to fast HBr + HOBr recycling (Reaction R30) ($\gamma_{HOBr} = 0.2$ in GEOS-Chem compared to $\gamma_{HOBr} = 0.02$ in p-TOMCAT for aqueous aerosol), with no springtime emissions of Br$_2$, from sea ice. The spring shift in GEOS-Chem (relative to the winter maximum at northern mid-latitudes) is due to the need for some insolation to drive HOBr production. p-TOMCAT simulates a spring maximum with slower HBr + HOBr recycling by including a blowing-snow source for Br$_2$, (Yang et al., 2008, 2010). The Arctic column amounts in GEOS-Chem are dominated by the free troposphere, while those in p-TOMCAT have a large boundary layer contribution. In-situ observations of BrO during the ARCTAS aircraft campaign over Alaska in April 2008 found significant mixing ratios in the free troposphere, with a mean of $\sim 2$ pmol mol$^{-1}$ (Salawitch, et al., 2010). In comparison, GEOS-Chem simulates a 09:00–17:00 LT mean of 1.3 pmol mol$^{-1}$ BrO for the Arctic free troposphere in April. Both models likely oversimplify photochemistry in polar spring, as local emissions of
Br\textsubscript{y} and the extent of heterogeneous recycling remain poorly constrained (Simpson et al., 2007).

Figure 5 shows little seasonal variation of BrO column in the tropics, either in the observations or the models. The models are too low. Observations at southern mid-latitudes show concentrations comparable to northern mid-latitudes (confirming the dominant natural origin of Br\textsubscript{y}) but weaker seasonal dependence as might be expected from lower aerosol concentrations to drive (Reaction R30).

5 Impact on tropospheric ozone and OH

Tropospheric bromine chemistry drives several catalytic cycles for ozone loss in the troposphere. The three most important are:

**Mechanism 1: BrO + HO\textsubscript{2}**

\[
\begin{align*}
\text{Br} + \text{O}_3 &\rightarrow \text{BrO} + \text{O}_2 \quad \text{(R5)} \\
\text{BrO} + \text{HO}_2 &\rightarrow \text{HOBr} + \text{O}_2 \quad \text{(R14)} \\
\text{HOBr} + h\nu &\rightarrow \text{Br} + \text{OH} \quad \text{(R25)} \\
\text{net: } &\text{O}_3 + \text{HO}_2 \rightarrow \text{OH} + 2\text{O}_2 \\
\end{align*}
\]

with closure for the hydrogen oxide radicals (HO\textsubscript{x} \equiv OH + H + HO\textsubscript{2} + organic peroxy and oxy radicals) provided for example by oxidation of CO.

\[
\text{CO} + \text{OH} \rightarrow \text{CO}_2 + \text{HO}_2. 
\]

**Mechanism 2: BrNO\textsubscript{3} + H\textsubscript{2}O**

\[
\begin{align*}
\text{Br} + \text{O}_3 &\rightarrow \text{BrO} + \text{O}_2 \quad \text{(R5)} \\
\text{BrO} + \text{NO}_2 + \text{M} &\rightarrow \text{BrNO}_3 + \text{M} \quad \text{(R20)} \\
\text{BrNO}_3 &\rightarrow \text{HOBr} + \text{HNO}_3 \quad \text{(R29)} \\
\text{HOBr} + h\nu &\rightarrow \text{Br} + \text{OH} \quad \text{(R25)} \\
\text{net: } &\text{O}_3 + \text{NO}_2 + \text{H}_2\text{O}(\text{aq}) \rightarrow \text{O}_2 + \text{HNO}_3 + \text{OH}. \\
\end{align*}
\]

**Mechanism 3: HOBr + HBr**

\[
\begin{align*}
\text{Br} + \text{O}_3 &\rightarrow \text{BrO} + \text{O}_2 \quad \text{(R1)} \\
\text{BrO} + \text{HO}_2 &\rightarrow \text{HOBr} + \text{O}_2 \quad \text{(R2)} \\
\text{Br} + \text{RH} \rightarrow \text{HBr} + \text{RO}_2 \quad \text{(R5–R10)} \\
\text{HOBr} + \text{HBr} &\rightarrow \text{Br}_2 + \text{H}_2\text{O} \quad \text{(R30)} \\
\text{Br}_2 + h\nu &\rightarrow 2\text{Br} \quad \text{(R23)} \\
\text{net: } &\text{O}_3 + \text{HO}_2 + \text{RH} \rightarrow \text{O}_2 + \text{H}_2\text{O} + \text{RO}_2. \\
\end{align*}
\]

A common step in all three mechanisms is the formation of HOBr. Loss of HOBr is either by photolysis or by reaction with HBr (Fig. 3), and both of these sinks drive catalytic ozone loss (Mechanisms 1 and 3). Thus Br-catalyzed ozone loss is limited by the rate of HOBr production. This is in contrast to the polar springtime boundary layer, where the BrO + BrO self-reaction is the dominant catalytic ozone sink due to very high BrO concentrations. We see from Fig. 3 that the self-reaction of BrO is 50 times slower than the reaction with HO\textsubscript{2} on the global scale. The BrO + HO\textsubscript{2} Reaction (R14) accounts for 95 % of global tropospheric HOBr production while BrNO\textsubscript{3} hydrolysis accounts for the rest. Since 92 % of HOBr is photolyzed, Mechanism 1 is responsible for about 90 % of Br-catalyzed ozone loss. However, Mechanism 2 has the important secondary effect of providing a sink for NO\textsubscript{x} and thus slowing down ozone production.

Table 3 shows the global impact of bromine chemistry on the tropospheric ozone budget. The budget is calculated following standard procedure as that of the odd oxygen family: O\textsubscript{x} \equiv O\textsubscript{3} + NO\textsubscript{2} + 2NO\textsubscript{3} + peroxyacylnitrates + HNO\textsubscript{4} + 3N\textsubscript{2}O\textsubscript{5} + HNO\textsubscript{3} + BrO + BrNO\textsubscript{2} + 2BrNO\textsubscript{3} (Crutzen and Schmailzl, 1983; Wu et al., 2007) to account for fast cycling of minor species with ozone. The tropospheric production rate of ozone in GEOS-Chem decreases by 4.1 % when bromine chemistry is included, and the ozone lifetime decreases by 2.9 %. We find a 6.5 % decrease in the global tropospheric ozone burden.

We see from Table 3 that bromine chemistry also causes a 4 % decrease in the global concentration of OH, the main tropospheric oxidant. This appears to mainly reflect the decreases in ozone and NO\textsubscript{x}, and is partly compensated by the source of OH from Mechanism 2. Applying our global mean fields of OH and temperature with kinetics from Sander et al. (2011), we calculate a methylchloroform tropospheric OH\textsubscript{5} lifetime against oxidation by OH in GEOS-Chem of 4.79 yr with bromine and 4.65 yr without. Though both are shorter than estimates from observations, 5.5 to 6 yr (Spivakovsky et al., 2000; Prinn et al., 2005), bromine decreases the model bias. Fast conversion of HO\textsubscript{2} to H\textsubscript{2}O in aerosols, not included in our GEOS-Chem version, could fully correct the bias (Mao et al., 2010, 2012).

Figure 6 shows the seasonal zonal mean decreases in tropospheric ozone mixing ratios due to bromine chemistry. Concentrations decrease by < 1–8 nmol mol\textsuperscript{-1} depending on region and season. The impact is largest in the northern extratropics in spring, reflecting a combination of elevated BrO (Fig. 5) and ozone. The general increase with latitude in the effect of bromine on ozone is consistent with the previous model studies of von Glasow et al. (2004) and Yang et al. (2010). We find little zonal variability in the effect.

A number of studies have previously evaluated the global ozone simulation in GEOS-Chem with observations from surface sites, sondes, and satellites (Sauvage et al., 2007; Nassar et al., 2009; Zhang et al., 2010). These have shown patterns of over- and underestimates that can vary.
Table 3. Global tropospheric ozone (O\textsubscript{3}) budget in GEOS-Chem\textsuperscript{a}.

| Chemical production, \(P(O_{3})\) Tg a\textsuperscript{-1} | Chemical loss, \(L(O_{3})\) Tg a\textsuperscript{-1} | Deposition Tg a\textsuperscript{-1} | STE\textsuperscript{b} Tg | Tropospheric burden Tg | Lifetime days | \(10^{6}\) molecules cm\textsuperscript{-3} | [OH] |
|----------------------------------------------------------|---------------------------------|-----------------|-----------------|-----------------|----------------|-----------------|-----|
| No bromine                                               | 5110                            | 4480            | 948             | 349             | 370            | 27.8            | 1.23 |

\textsuperscript{a} Global annual mean budget for the odd oxygen \((O_{3})\) chemical family defined as \(O_{3} = O_{3} + NO_{2} + 2NO_{3} + peroxyacetyl nitrates + HNO_{3} + 3N_{2}O_{5} + HNO_{3} + BrO + BrNO_{2} + 2BrNO_{3}\) (Crutzen and Schmailzl, 1983; Wu et al., 2007), with molecular weight taken to be that of ozone.

\textsuperscript{b} Stratosphere-to-troposphere exchange is inferred from mass-balance: \(\text{STE} = L(O_{3}) + \text{Deposition} - P(O_{3})\).

Figure 6. Decrease in tropospheric ozone (nmol mol\textsuperscript{-1}) from bromine chemistry. The figure shows zonal seasonal mean differences between GEOS-Chem simulations including vs. not including bromine chemistry. Shading indicates the stratosphere.

Figure 7. Mean seasonal variation of 19th-century ozone in surface air at Montsouris, France (50\textdegree N, 2\textdegree E), 1876–1886 observations reanalyzed by Volz and Kley (1988) (black) are compared to preindustrial model simulations using GEOS-Chem (red) and p-TOMCAT (blue), with bromine chemistry (solid) and without (dotted).

6 Impact on pre-industrial ozone and radiative forcing

A long-standing problem in global modeling of tropospheric ozone has been the inability of models to reproduce the very low ozone concentrations measured in surface air worldwide at the turn of the 20th century (Wang and Jacob, 1998; Mickley et al., 2001; Shindell et al., 2003; Lamarque et al., 2005; Horowitz, 2006). Calibration of these older measurements is controversial (Marenco et al., 1994) but the Montsouris (Paris) measurements are considered reliable (Volz and Kley, 1988). To examine the potential for bromine chemistry to address this discrepancy we conducted a GEOS-Chem sensitivity simulation for the pre-industrial atmosphere removing all anthropogenic sources (including \(NO_{x}\) from fertilizer use), and reducing methane from 1700 to 700 nmol mol\textsuperscript{-1}. We decreased biomass burning to 10\% of its present value (Wang and Jacob, 1998), though this has little impact on our results. Bromine sources were held to present-day estimates, except for \(CH_{3}Br\) and the stratospheric boundary condition. We used 5 pmol mol\textsuperscript{-1} \(CHBr_{3}\) in surface air worldwide based on ice core records (Saltzman et al., 2004). Mixing ratios of stratospheric \(Br_{y}\) species were scaled from a total of 22 to 12 pmol mol\textsuperscript{-1} \(Br_{y}\) (Liang et al., 2010; Montzka et al., 2011). Sea salt debromination rates may have increased between the preindustrial and present-day due to enhanced particle acidity from anthropogenic emissions (Sander et al., 2003) but this effect is not considered here.
Figure 7 compares the 1876–1886 Montsouris observations to simulated pre-industrial ozone from GEOS-Chem and p-TOMCAT (Yang et al., 2010), with and without bromine chemistry. p-TOMCAT applies similar conditions to GEOS-Chem for simulating the pre-industrial atmosphere. The simulations without bromine chemistry overestimate the mean observed ozone by 6.2 and 3.1 nmol mol\(^{-1}\) in GEOS-Chem and p-TOMCAT respectively. Both simulations show a seasonal maximum in late winter and early spring, which is a standard extratropical feature in models of natural ozone (Wang and Jacob, 1998; Monks, 2000; Mickley et al., 2001) but is not seen in the Montsouris observations. Including bromine chemistry decreases annual mean ozone at Montsouris by 2.6 and 1.9 nmol mol\(^{-1}\) in GEOS-Chem and p-TOMCAT respectively. Both simulations to simulated pre-industrial ozone from GEOS-Chem and p-TOMCAT (Yang et al., 2010), with and without bromine chemistry, respectively, effectively correcting the overestimate in p-TOMCAT and reducing it substantially in GEOS-Chem. The decrease is least in summer (0.9–1.4 nmol mol\(^{-1}\)) and greatest in winter-spring (2.3–5.1 nmol mol\(^{-1}\)), which suppresses the winter-spring maximum in both models. Although there are significant differences in simulated ozone between GEOS-Chem and p-TOMCAT, the impact of bromine chemistry on both models is consistent.

Saiz-Lopez et al. (2012) recently suggested that halogen chemistry could reduce the radiative forcing from anthropogenic tropospheric ozone since pre-industrial times by −0.1 W m\(^{-2}\) or about 30 %. However, they only considered the impact of this chemistry on the present-day atmosphere. Considering that tropospheric halogens are mainly natural, they would also decrease ozone in the pre-industrial atmosphere. We find in GEOS-Chem that although the sources of bromine are similar in the present and pre-industrial atmospheres, the chemistry differs in two principal ways. First, lower methane in the pre-industrial atmosphere leads to lower CH\(_2\)O and hence suppressed production of HBr by Reaction (R5). Second, lower aerosol loadings suppress the HBr + H\(_2\)O heterogeneous Reaction (R30). These two effects have competing influences on tropospheric BrO and we find in GEOS-Chem that they largely cancel. Thus the effects of bromine chemistry on ozone are similar in the present-day and pre-industrial atmospheres. We find that the increases in the total tropospheric ozone burden from pre-industrial to present are 119 and 113 Tg in the simulations without and with bromine chemistry, respectively. Considering that the radiative forcing from tropospheric ozone depends roughly linearly on the change in burden (Mickley et al., 1999), we conclude that bromine chemistry decreases ozone radiative forcing by about 5 %.

The impact of bromine chemistry on pre-industrial US surface ozone is of interest because this natural background represents a policy reference point for assessing the risk associated with anthropogenic emissions (US Environmental Protection Agency, 2006). Zhang et al. (2010) recently reported a mean natural ozone background in US surface air of 18 ± 6 nmol mol\(^{-1}\) using a high-resolution version of GEOS-Chem. We find in our simulation that bromine chemistry decreases natural surface ozone over the US from 16 to 13 nmol mol\(^{-1}\) on an annual mean basis, i.e., an effect of 3 nmol mol\(^{-1}\) or 19 %.

7 Implications for the atmospheric lifetime of mercury

Mercury in the atmosphere is mostly emitted as gaseous Hg(0), and is removed by oxidation followed by rapid deposition of the water-soluble Hg(II) compounds (Lindberg et al., 2007). The observed atmospheric variability of Hg(0) implies a lifetime against deposition of 0.5–1 yr, with a possibly shorter lifetime against oxidation depending on whether atmospheric Hg(II) can be reduced back to Hg(0) (Slemr et al., 1981, 1985; Bergan et al., 1999; Holmes et al., 2010). Most models of atmospheric mercury have assumed that oxidation of Hg(0) is driven by OH and ozone, but these reactions are now thought to be too slow to be of atmospheric relevance (Calvert and Lindberg, 2005; Hynes et al., 2009). Goodsite et al. (2004) showed that rapid oxidation of Hg(0) to Hg(II) by Br atoms could take place by

\[
\text{Hg} + \text{Br} + \text{M} \rightarrow \text{HgBr} + \text{M} \quad (R31)
\]

\[
\text{HgBr}^+ \rightarrow \text{Hg} + \text{Br} \quad (R32)
\]

\[
\text{HgBr} + \text{X} \rightarrow \text{HgBrX} \quad , \quad (R33)
\]

where \(\text{X}\) is a radical, such as OH or Br, that converts unstable Hg(I) to stable Hg(II) in a 3-body reaction. Under tropospheric conditions, Reaction (R31) operates in the low-pressure limit whereas Reaction (R33) operates in the high-pressure limit (Goodsite et al., 2004, 2012; Donohue et al., 2006). Using the kinetic data from Goodsite et al. (2004) and Donohue et al. (2006), together with Br concentration fields from the p-TOMCAT model (Yang et al., 2005) and OH fields from GEOS-Chem, Holmes et al. (2006, 2010) showed that oxidation by Br atoms could represent the dominant global atmospheric sink for Hg(0). Here we revisit this calculation using our computed Br concentrations and draw implications for possible changes in the Hg(0) atmospheric lifetime between pre-industrial and present conditions.

The lifetime \(\tau\) of Hg(0) against oxidation to Hg(II) by Reactions (R31)–(R33) can be expressed assuming HgBr steady state by Holmes et al. (2006):

\[
\tau = \frac{k_{32} + k_{33,Br}[\text{Br}] + k_{33,OH}[\text{OH}]}{k_{31}[\text{Br}][\text{M}](k_{33,Br}[\text{Br}] + k_{33,OH}[\text{OH}]},
\]

where we have assumed that \(\text{X}\) in Reaction (R33) can be either Br or OH, following Holmes et al. (2006, 2010). Using the kinetic data of Holmes et al. (2010) with updates from Goodsite et al. (2012), and assuming a uniform tropospheric Hg(0) concentration, we derive from our GEOS-Chem model fields a global tropospheric Hg(0) lifetime of 0.58 yr against oxidation by Br. In comparison, Holmes et al. (2010) calculated a lifetime of 0.50 yr in a GEOS-Chem Hg(0) simulation.
using the Yang et al. (2005) Br mixing ratios in the free troposphere and assuming 1 pmol mol$^{-1}$ BrO in the marine boundary layer. We repeated our calculation using their archived Br and OH fields and obtain a lifetime of 0.41 yr with the Holmes et al. (2010) kinetics, and 0.65 yr with the kinetics update from Goodsite et al. (2012). Our estimate of 0.41 yr can be viewed as consistent with the Holmes et al. (2010) estimate of 0.50 yr in view of the uncertainty involved with assuming a uniform Hg(0) concentration. Our 11 % shorter lifetime (0.58 vs. 0.65 yr) reflects a 13 % greater mean tropospheric Br concentration in our GEOS-Chem simulation.

The mean tropospheric Br atom concentration in our pre-industrial simulation is 38 % greater than present-day due to lower ozone suppressing the Br + O$_3$ Reaction (R4). This increase in Br causes the Hg(0) lifetime against oxidation to decrease to 0.35 yr, 40 % lower than present-day. Our work thus suggests that the increase in ozone since pre-industrial times may have increased the atmospheric residence time of Hg(0) by 66 %. With an atmospheric lifetime of four months, mercury in pre-industrial times would be less of a global pollutant than today. Most of the observed increase in ozone has taken place since 1950 (Marenco et al., 1994), by which time there had already been large anthropogenic mercury emissions at northern mid-latitudes from mining, industry, and combustion (Streets et al., 2011).

Our work highlights a potentially important link between ozone trends and the lifetime of Hg(0) through partitioning of the Br$_x$ family. This result is contingent on Br playing a dominant role in Hg(0) oxidation. Changes in sea salt debromination between the preindustrial and present as well as our simplified treatment of heterogeneous bromine chemistry represent additional uncertainties that might affect our Hg(0) lifetime estimates.

8 Conclusions

We have developed a simulation of tropospheric bromine coupled to oxidant-aerosol chemistry in the GEOS-Chem global chemical transport model (CTM). Our goal was to better understand the effect of bromine chemistry on tropospheric ozone and mercury, for both the present and pre-industrial atmospheres.

We found that standard gas-phase mechanisms for bromine chemistry are unable to reproduce observed levels of tropospheric BrO, including the latitudinal and seasonal variations reported in the new GOME-2 satellite product of Theys et al. (2011). Considerable improvement is achieved by including in GEOS-Chem the HOBr+HBr reaction in aerosols. This brings model BrO into the observed range and reproduces major features of the satellite observations including the increase with latitude and the seasonal maxima in northern mid-latitudes in winter and in the Arctic in spring. Laboratory studies provide ample evidence for the HOBr+HBr reaction but offer limited quantitative information to constrain models. The reactive uptake probability approach used here (γ = 0.2 for sulfate and sea-salt aerosols, γ = 0.1 for ice crystals) is probably too simplistic. There is a need to better characterize this reaction over a range of aerosol types and temperatures relevant to the troposphere.

Tropospheric bromine chemistry in GEOS-Chem decreases the present-day global burden of tropospheric ozone by 6.5 %. This is due in part to loss of NO$_x$ by BrNO$_3$ formation and hydrolysis, and in part to catalytic loss of ozone by HOBr formation and photolysis. Ozone mixing ratios decrease by < 1–8 nmol mol$^{-1}$ depending on region and season, with the largest effects in the extratropical Northern Hemisphere in spring. The global mean OH concentration decreases by 4 %. These changes in ozone and OH appear to ameliorate previous GEOS-Chem biases in comparisons to observations, although more work is needed to evaluate the simulation of ozone.

We find that bromine chemistry significantly improves the ability of global models to reproduce surface ozone observations from the turn of the 20th century. BrO concentrations in GEOS-Chem are comparable in the present-day and pre-industrial atmospheres, as the effect of decreased methane (suppressing the BrO$_x$ sink from the CH$_2$O+Br reaction) is compensated by the effect of decreased aerosol (suppressing the BrO$_x$ source from the HBr+HOBr reaction). Comparison of pre-industrial simulations with the GEOS-Chem and p-TOMCAT CTMs to 1876–1886 observations at Montsours (France) show mean overestimates of 6 nmol mol$^{-1}$ in GEOS-Chem and 3 nmol mol$^{-1}$ in p-TOMCAT without bromine chemistry. Including bromine chemistry has similar effects in both models, fully correcting the bias relative to observations in p-TOMCAT and reducing it by half in GEOS-Chem. It suppresses the winter-spring model maximum, better representing the aseasonal behavior of the observations. Bromine chemistry in GEOS-Chem decreases the natural surface ozone background over the US by 3 nmol mol$^{-1}$ on an annual mean basis, a significant increment when assessing the effect of anthropogenic emissions on ozone exposure. Because the effect of bromine chemistry on ozone is similar in the present-day and pre-industrial atmospheres, we find that the global radiative forcing from anthropogenic tropospheric ozone is negligibly affected. However, the impact on radiative forcing may be sensitive to changes in sea salt debromination and assumptions about heterogeneous chemistry that require further investigation.

In contrast to the similarity between BrO concentrations in the pre-industrial troposphere and present-day, we find that Br atom concentrations are 40 % higher (global mean) in the pre-industrial troposphere because of lower ozone. It has been hypothesized that Br could provide the main atmospheric oxidant for conversion of elemental mercury Hg(0) to Hg(II), with a linear-to-quadratic dependence on Br concentrations (Holmes et al., 2006, 2010). If so, anthropogenic ozone would have an important impact on the atmospheric lifetime of mercury. Based on best estimates for
Hg-Br kinetics, we find in GEOS-Chem that the lifetime of Hg(0) against oxidation to Hg(II) by Br atoms was 4 months in the pre-industrial atmosphere as compared to 7 months at present. Most of the anthropogenic increase in tropospheric ozone has taken place since 1950, and background surface ozone concentrations at northern mid-latitudes have continued to increase in recent decades. Thus historical mercury emissions from human activity (mining, industry, combustion) may not have dispersed globally to the extent previously thought, but instead deposited mostly to the northern mid-latitudes. This could possibly explain observations of elevated mercury in North Atlantic subsurface waters (Sørensen et al., 2010) and the recent trend of decreasing atmospheric concentrations over the North Atlantic (Slemr et al., 2011). It should be emphasized, however, that the role of Br as a global mercury oxidant remains hypothetical. Our results stress the need for further research to better establish this role.
