Abstract: Severe, life-threatening adverse reactions to capecitabine sometimes occur in the treatment of solid tumors. Screening for dihydropyrimidine dehydrogenase (DPYD) deficiency is encouraged before start of treatment, but the genetic variants that are commonly analyzed often fail to explain toxicities seen in clinical practice. Here we describe the case of a 79-year-old Caucasian female with breast cancer who presented with life-threatening, rapidly increasing toxicity after 1 week of treatment with capecitabine and for whom routine genetic DPYD test resulted negative. DPYD exon sequencing found variant c.2242+1G>T at the donor splicing site of exon 19. This variant is responsible for skipping of exon 19 and subsequent generation of a non-functional DPYD enzyme. This variant has not been described previously but was found in three other members of the patient’s family. With this case, we show that exon sequencing of DPYD in patients who experience marked toxicity to fluoropyrimidines and test negative for commonly evaluated variants can prove extremely useful for identifying new genetic variants and better explain adverse reactions causality.

Keywords: pharmacogenetics, adverse drug reaction, fluoropyrimidine, breast cancer

Introduction

Capecitabine is an oral prodrug of 5-fluorouracil (5-FU) that is rapidly and extensively absorbed in the intestine before conversion to 5-FU.1 Severe, life-threatening, and even fatal toxicity has been associated with deficient dihydropyrimidine dehydrogenase (DPYD) activity in patients receiving fluoropyrimidine-based chemotherapy at standard doses.2 Capecitabine-induced adverse reactions include severe hand-foot syndrome, gastrointestinal toxicity, hematological toxicity, and cardiotoxicity.3,4

Low DPYD activity is partly explained by genetic variability in the DPYD gene, which is highly polymorphic.5,6 However, only a few variants (ie, rs3918290 [DPYD*2A], rs55886062 [DPYD*13], and rs67376798) have been clearly associated with severe toxicity to fluoropyrimidines. In our hospital, genotyping of these three variants is available on request for patients starting fluoropyrimidine therapy and has proved to be cost-effective.7 Nonetheless, this test enables us to avoid only 10%–15% of capecitabine-related severe adverse reactions, thus strongly suggesting that other genetic variants in DPYD or in other genes might also be implicated.8 DPYD phenotyping based on the measurement of the enzyme activity in peripheral blood mononuclear cells is another proposed approach to minimize life-threatening toxicity.9 It is yet to be discerned which of these approaches offers the better predictive value and is the most cost-effective to implement or whether a combination of both would be the preferred choice.

Case report
A 79-year-old Caucasian woman was diagnosed with poorly
differentiated carcinoma that appeared to have originated in
breast tissue. She underwent a second-line chemotherapy
based on capecitabine (2 weeks on and 1 week off, total dose
of 2,600 mg/day in days 1–14).

After 8 days of treatment, she visited the emergency room
with progressive asthenia, grade 1 diarrhea, and grade 1 mucosi-
tis and was discharged after parenteral fluid support and intensive
treatment with loperamide. Capecitabine was discontinued after
48 hours (cumulative dose 26 g) owing to rapidly increasing tox-
icity despite oral rehydration and a standard dose of loperamide.
The main symptoms were diarrhea (grade 2), nausea (grade 2),
odynophagia (grade 2), severe solid dysphagia, painful mucositis
(grade 3), and progressive asthenia (grade 2) associated with
low-grade fever. She was admitted to hospital immediately for
close monitoring with intensive fluid and nutritional support,
broad-spectrum antibiotics (piperacillin-tazobactam, vancomy-
cin, and fluconazole), and pain relievers.

Both hematological toxicity (grade 4 neutropenia and
grade 2 thrombocytopenia) and non-hematological toxicity
(grade 1 palmar-planter erythrodysthesia, grade 2 diarrhea,
and grade 3 mucositis) worsened rapidly. Her white
blood cell count dropped, reaching a zero nadir at day +16
and remaining unchanged for over 6 days despite treatment
with granulocyte colony-stimulating factor. The patient also
developed anemia requiring erythrocyte and platelet transfu-
sions. Her platelet nadir started to recover slowly at day +17.

Besides support with blood derivatives, she required third-
step analgesia with strong opioids (morphine infusion pump)
and intensive nutritional support with parenteral nutrition.
The consequences of the severe mucositis and diarrhea resulted in
low blood levels of potassium, calcium, phosphate, magne-
sium, and protein, with significant weight loss (up to 5 kg).
In addition, the international normalized ratio was increased,
with normal liver transaminases. Hand-foot syndrome pro-
gressed more slowly during hospitalization, with progressive,
painful swelling and numbness on the palms and soles (up
to grade 2), together with progressive alopecia that started
20 days after the withdrawal of capecitabine and lasted for
more than 3 months. After 23 days in hospital, the patient was
discharged with oral nutritional supplements that were neces-
sary for over 2 months until she could tolerate a normal diet.

DPYD deficiency was suspected as a potential explana-
tion for the life-threatening toxicity that developed after
such a short interval of exposure to fluoropyrimidines, in
the absence of liver or renal dysfunction and other potential
drug interactions. The patient did not receive treatment with
fluoropyrimidines again. After two further chemotherapy
lines, first cyclophosphamide+ zolendronic acid and later
vinorelbine, the patient died due to disease progression.

A routine genetic *DPYD* test was carried out in our hospi-
tal because of the strong suspicion of DPYD deficiency. The
three *DPYD* single-nucleotide polymorphisms (SNPs) were
genotyped according to the recommendations of the Clinical
Pharmacogenetics Implementation Consortium at the time.10
The SNPs were genotyped using real-time PCR and TaqMan
probes. None of the three variants were detected. However,
the presence of a DPYD deficit continued to be suspected.
Therefore, after receiving written informed consent, we
performed complete sequencing of the 23 *DPYD* exons.
A total of 23 pairs of oligonucleotides (Table 1) were used to
amplify and sequence *DPYD* exons. We identified two vari-
ants in *DPYD* exons, c.1601G>A (rs1801158, p.Ser534Asn,
*DPYD*4) and a previously unreported splice site mutation
at position 2242+1G>T, after the end of exon 19 (Figure 1).
This variant was most probably affecting splicing as confirmed
using Human Splicing Finder v3.1.11

The effect of this second SNP on the donor splicing
site was analyzed. RNA was isolated from peripheral blood
mononuclear cells and processed to cDNA. A cDNA frag-
ment from exon 18–20 was amplified using specific primers
(forward [5′-TTAAAATCTGATGGCACACCTTG] and
reverse [5′-TGCTTTTCAGATAAACCGAPGCCT]). PCR
product sizes were estimated using electrophoresis. Sequenc-
ing of PCR products revealed skipping of exon 19 of *DPYD*
in the patient’s mRNA (Figure 2). DPYD generated a truncated
protein of 795 amino acids lacking the correct sequence from
767 to the end (1025) (Figure 3). This region is considered
essential for the functionality of the protein because it is
part of the pyrimidine-binding domain (from 525 to 847).12

Due to the interest of this novel discovery and its potential
clinical implications, genotyping of the mutation was later
performed in the patient’s offspring: one son, one daughter,
and one granddaughter (a daughter descendant). For this
purpose, a TaqMan probe was synthesized for 2242+1G>T.
All individuals carried the 2242+1G>T mutation in hetero-
yzogosis. None of them presented the *DPYD*4 four allele.

DPYD phenotype assessment was performed by pretreat-
ment measurement of plasma uracil (U) and dihydrouracil
(UH2) in the descendents.13 Unfortunately, we were not able
to analyze a sample from the original patient because at the
time this analysis was performed, she was already deceased.

Two samples showed DPYD deficiency according to
established criteria (uracil concentration >16 ng/mL and/or
UH2/U ratio <6). The patient showed values that
Novel DPYD variant causes severe toxicity to capecitabine

were close to the limit but within the normal activity range. Phenotyping results are shown in Table 2.

A TaqMan probe was synthesized for genotyping of 2242+1G>T in a cohort of 487 anonymous DNA samples from colorectal cancer patients (mainly Caucasians from Iberian ancestry). None of the samples analyzed, except that of the present case, carried this mutation, indicating that it is a rare variant in our setting.

The severe toxicity can be explained by the presence of the variant c.2242+1G>T, which generates shorter mRNA and protein, thus rendering a non-functional DPYD protein that lacks a sequence in the pyrimidine-binding domain (Figure 3). The SNP is just located in the first nucleotide after the end of exon 19. Other DPYD variants affecting donor splicing sites have also demonstrated skipping of the corresponding exon12,14 or generation of an in-frame insertion of small fragments causing severe and occasionally fatal adverse reactions to fluoropyrimidine.15

In this patient, a non-synonymous variant, c.1601G>A (rs1801158, p.Ser534Asn), was also observed. This variant defines the DPYD* four allele and decreases protein activity by 20%. However, although this allele has previously been related to the risk of fluoropyrimidine-induced toxicity,16,17 a recent meta-analysis did not find any significant association between c.1601G>A and severe fluoropyrimidine-induced toxicity.18 The DPYD deficiency observed in two out of three members of the family carrying the c.2242+1G>T mutation supports the effect of this variant on the fluoropyrimidine metabolism. The fact that none of them presented variant c.1601G>A further backs the theory that this new variant may be responsible for the descent in activity. As previously described, individuals carrying one functional and one non-functional allele of DPYD are likely to display a partial deficiency with 1.5 < UH2/U < 6. The third family member carrying this mutation showed a UH2/U ratio within the normal activity range, although close to the limit (6.6). This could be explained by factors not studied, such as copy number variants increasing the activity of the functional allele, or additional mutations in the other members.

The frequency of the DPYD variant c.2242+1G>T variant is lower than 0.002% in our setting, which suggests that it is a rare variant and its inclusion in our routine genotyping tests would not significantly increase their predictive value. Testing for this variant in other populations (since our sample is mainly integrated by Caucasian individuals of...
Iberian ancestry) would be very interesting as it could help to investigate its possible origins. This is definitely a line of investigation to be pursued in future works.

Conclusion

We consider the newly described variant 2242+1G>T in DPYD to be the most probable cause of very severe toxicity following the first cycle of treatment with capecitabine in a patient with breast cancer. DPYD phenotyping in patient’s offspring carrying the mutation showed decreased enzymatic activity, further supporting this conclusion. Whole DPYD sequencing is an interesting approach for the identification of causal variants in patients with suspected DPYD deficiency in whom routine DPYD tests yield negative results.

Ethics

Written informed consent was obtained from the three patient’s family members that were tested for DPYD deficiency and from all patients in the colorectal cancer cohort that were tested for the presence of c.2242+1G>T. Written informed consent from the patient’s next of kin was provided to have this case published since the patient was deceased at that time.

Acknowledgments

We would like to thank Luis Fernández Pacios at Universidad Politécnica de Madrid, for his support in modeling the DPYD 3D structure. The study was partially supported by the Ministry of Economy and Competitiveness grant PTA2013-8539-I (MIG), ISCIII-FIS grant PI12/00056, “Programa Miguel Servet II grant MSII13/00008” (LALF), and by “Consejería de Educación y Deporte de la Comunidad de Madrid” grant PEJ15/BIO/TL-0603 (CB) and PEJ16/MED/AI-1260 (LALF). All grants were cofunded by the European Regional Development Fund (ERDF [Fondo Europeo de Desarrollo Regional]) Funds from the European Commission “A way of making Europe.” XGG was supported by a grant from Gregorio Marañón Health Research Institute.
