Abstract

The fair-ranking problem, which asks to rank a given set of items to maximize utility subject to group fairness constraints, has received attention in the fairness, information retrieval, and machine learning literature. Recent works, however, observe that errors in socially-salient (including protected) attributes of items can significantly undermine fairness guarantees of existing fair-ranking algorithms and raise the problem of mitigating the effect of such errors. We study the fair-ranking problem under a model where socially-salient attributes of items are randomly and independently perturbed. We present a fair-ranking framework that incorporates group fairness requirements along with probabilistic information about perturbations in socially-salient attributes. We provide provable guarantees on the fairness and utility attainable by our framework and show that it is information-theoretically impossible to significantly beat these guarantees. Our framework works for multiple non-disjoint attributes and a general class of fairness constraints that includes proportional and equal representation. Empirically, we observe that, compared to baselines, our algorithm outputs rankings with higher fairness, and has a similar or better fairness-utility trade-off compared to baselines.

1 Introduction

Given a query and a set of $m$ items, ranking problems require one to output an ordering of a small subset of items in decreasing order of relevance to the query. Such ranking problems have been extensively studied in the information retrieval [46] and the machine learning [45] literature, and algorithms for them are used in applications such as search engines, personalized feed generators, and online recruiting platforms [44][12][8]. Several studies have observed that when the outputs of ranking algorithms are consumed by end-users, e.g., image results for occupation-related queries, articles with different political leanings, and job applicants in online recruiting, the outputs can mislead or alter their perceptions about socially-salient groups [38], polarize their opinions [24, 50], and affect economic opportunities available to individuals [32]. A reason is that relevance (or utilities) input to ranking algorithms may be influenced by human or societal biases, leading to output rankings that skew representations of socially-salient, and often legally-protected, groups such as women and Black people [55].

A growing number of works aim to make the output of ranking algorithms fair with respect to socially-salient attributes [74][75][58]. As for notions of fairness, in the case when each item belongs to one of two socially-salient groups ($G_1$ or $G_2$), equal representation requires that, for every $k$, (roughly) $\frac{k}{2}$ items from each of $G_1$ and $G_2$ appear in the first $k$ positions of the output ranking. Proportional representation requires that at most $k\cdot \frac{|G_1|}{m}$ items from each $G_1$ appear in the first $k$ positions. Fairness criteria that generalize proportional representation and involve $p \geq 2$ groups $G_1, \ldots, G_p$, where each item may belong to multiple groups, have also been considered: Given values $U_{k\ell}$, they require that at most $U_{k\ell}$ items from $G_\ell$ appear in the first $k$ positions of the output ranking [61][18]. One set of works in the fair-ranking literature tries to improve fairness in utility-estimation [72][62][73][51]. Such approaches have the benefit that no changes to the existing ranking algorithm are necessary but they may be unable to guarantee that the output ranking satisfies the required fairness criteria [27]. Another set of works use the given utilities as-is and change the ranking algorithm to output
We show that our fair-ranking framework, besides nearly satisfying the given fairness criteria, has a provably high utility (Theorem 4.1). Complementing Theorem 4.1, we prove near-tightness of the fairness guarantee (Theorem F.1). For equal representation fairness criteria, this results shows that it involves multiple overlapping groups when the socially-salient attributes are assumed to follow the probabilistic noise model mentioned above. In particular, it finds a utility maximizing ranking subject to satisfying the specified fairness criteria by including them as fairness constraints [61, 9, 18, 27, 30]. While these latter approaches can guarantee fairness, they require coming up with new algorithms to solve the arising constrained ranking problems. Both approaches, however, rely on knowledge of the socially-salient attributes of the items [56].

Assuming precise access to socially-salient attributes is reasonable in some contexts and has led to successful deployment of fair-ranking frameworks; see [27]. However, in several contexts, socially-salient attributes can be erroneous, missing, or known only probabilistically. For instance, errors can arise due to misreporting, which is a common concern with self-reported attributes [4]. Attributes can also be missing, as is the case with images in web-search or in settings where it is illegal to collect certain socially-salient attributes [20]. Often attributes are predicted using ML-classifiers, but such prediction has inaccuracies [10]. In such cases, one can calibrate the confidence scores of classifiers to derive (aggregate) probabilistic information about the true attributes [55]. Moreover, probabilistic information about socially-salient (protected) attributes can be sometimes computed from other attributes. For instance, name and location of an individual, combined with aggregate census data may be used to get a conditional distribution of their race [23, 56, 20]. Even accurate attributes may be randomly and independently flipped to preserve user privacy, and the distribution of flipped attributes is determined by public parameters of, e.g., the randomized response mechanism [37, 69].

Several models of inaccuracies in data have been proposed [47, 25]. We consider one such model (due to [5]) to capture inaccuracies in socially-salient attributes. Each item $i$ belongs to the $\ell$-th group with a known probability $P_{i\ell}$. For each item $i$, the distribution corresponding to $P_{i\ell}$ over groups is assumed to be independent of corresponding distributions of other items. This model can be used in cases where these probabilities are available or can be derived, as in some of the aforementioned examples (see Section 5 and Supplementary Material A). In other cases, e.g., when errors are strategic or adversarial, other models are needed. This model and its variants have also been used by works on designing fair algorithms in the presence of inaccuracies, for problems including classification [42, 67, 66, 14], subset selection [48], and clustering [25] (Supplementary Material B briefly discusses these works).

In this noise model, while socially-salient attributes are not explicitly specified, one could still use existing fair-ranking algorithms by first sampling groups for items from the given probabilities. Indeed, [29] evaluate existing fair-ranking algorithms on attributes obtained from the probabilities derived from ML classifiers. They find that “errors in [socially-salient attributes] can dramatically undermine fair-ranking algorithms” and can cause “non-disadvantaged groups” to become disadvantaged after a “fair” re-ranking.” We confirm this observation on a synthetic dataset when the goal is to finding a ranking that satisfies equal representation (Section 5.1). We assigned each item the socially-salient group that is most likely and find that when existing fair-ranking algorithms (for equal representation) are run with this group information, they output rankings that significantly violate the equal representation criteria (Figure 1). Further, we mathematically analyze two natural methods to sample groups from probabilities and give examples where taking such information as input, existing fair-ranking algorithms output rankings which provably violate the equal representation criteria (Supplementary Material C). Thus, new ideas are needed to design fair-ranking frameworks that can guarantee given fairness criteria under this noise model.

Our contributions. We present a fair-ranking framework that guarantees given fairness criteria when the socially-salient attributes are assumed to follow the probabilistic noise model mentioned above. In particular, it finds a utility maximizing ranking subject to a class of constraints that only rely on given probability distributions (Program 4.1). These constraints relax the given fairness criteria by a carefully chosen factor: for equal representation, the relaxation is by roughly a $1 + \frac{1}{\sqrt{k}}$ multiplicative factor for position $k$ for any $k$. Moreover, instead of sampling the attribute values and applying constraints on them, these constraints apply the relaxed-fairness criteria to the expected number of items from each group that appear in the first $k$ positions. We show that these constraints ensure that any ranking approximately satisfying the given fairness criteria is feasible for them and any ranking feasible for them approximately satisfies the given fairness criteria (Theorem 4.1). Our fair-ranking framework works for the general class of fairness criteria introduced earlier, which involve multiple overlapping groups $G_1, \ldots, G_p$ and upper bound $U_{k\ell}$ for the $\ell$-th group and $k$-th position (Theorem 4.1), and for their position-weighted versions (Theorem F.1). We show that our fair-ranking framework, besides nearly satisfying the given fairness criteria, has a provably high utility (Theorem 4.1). Complementing Theorem 4.1, we prove near-tightness of the fairness guarantee (Theorem 4.2). For equal representation fairness criteria, this results shows that it
is information theoretically impossible to output a ranking that violates this criteria by less than a
multiplicative factor of $1 + \tilde{O}(\frac{1}{\sqrt{k}})$ at the $k$-th position for any $k$. Finally, we give a polynomial-time
algorithm to approximately solve Program (7) (Theorem 4.3).

Empirically, we evaluate our framework on both synthetic and real-world data against standard
metrics like weighted-risk difference (RD) that measure deviation from specific fairness criteria
(Section 5). We compare its performance to key baselines \cite{18, 61, 27, 48} on both single and multiple
attributes. In all simulations, compared to baselines, our framework has a higher maximum fairness
(2-10\% for RD; Figures 1 to 3) and a similar/better fairness-utility trade-off (Figures 2, 8, 10 and 14
to 16).

2 Related work

Work on automated information retrieval dates back to 1940s \cite{43, 21}. Since then the IR literature has
devoted a significant effort in measuring relevance of items to specific queries across different tasks:
including, web search \cite{7}, personalization \cite{34}, and product rating \cite{22}; we also refer the reader to
\cite{46} and the references therein. In the last three decades, works in the ML literature have also made
significant contributions to relevance-estimation \cite{45}, by proposing methods that: (1) supplement
traditional IR approaches, e.g., by automatically tuning their—previously hard to tune—parameters
\cite{63} and by improving their efficiency through clustering-based techniques \cite{64, 8}, and (2) substitute
traditional IR approaches by neural-network based models to predict item relevance \cite{12, 11, 68, 8}.

Fair ranking. Existing works on the fair-ranking problem take diverse approaches: Among works that
de-bias utilities, different approaches include, post-processing the utilities so that the post-processed
utilities satisfy some fairness requirement \cite{71}, introducing a “fairness penalty” in the objective
function used to train learning-to-rank models \cite{62, 73, 49}, and modifying feature representations
generated by up-stream algorithms so that the utilities learned from the modified representations
satisfy some fairness requirements \cite{72}. Works that alter the ranking algorithms can also be further
categorized into those which satisfy the constraints for each ranking \cite{18, 70, 27, 30} and those that
satisfy the constraints in aggregate over multiple rankings \cite{61, 9}. Among aforementioned works,
\cite{49} uses a version of adversarial training to make (fair) learning-to-rank models robust to outliers but,
unlike this work, they require socially-salient attributes of items to be accurately known to specify
the “fairness penalty.” All of the other aforementioned works also need access to the socially-salient
attributes of items. When protected attributes are inaccurate, these works can fail to satisfy their
fairness and/or utility guarantees \cite{29}.

Effect of inaccuracies on fair-ranking algorithms. Some recent works have considered assessing
fairness of rankings and ranking algorithms with missing or inaccurate protected attributes \cite{39}
analyze the setting where all protected attributes are missing, but can be purchased at a fixed cost
per item. They give statistical-techniques to estimate the fairness-value of a given ranking at a small
cost. \cite{29} use ML-classifiers to infer protected attributes from real-world data and study performance
of the fair-ranking algorithm by \cite{28} when given inferred attributes as input. While these works
underscore the need for fair-ranking algorithms to be robust to inaccuracies in protected attributes,
they only assess fairness in the presence of noisy protected attributes.

3 Model of fair ranking with noisy attributes

Ranking problem. In ranking problems, given $m$ items, one has to select a subset of $n$ items and
output a permutation of the selected items. This permutation is said to be a ranking. There is a
large body of work on estimating the relevance of items and personalizing these estimates to specific
users/queries \cite{46, 45}. We consider a ranking problem where the relevance of items are known.
Abstracting relevance estimation, in this problem, one is given an $m \times n$ matrix $W$, such that placing
the $i$-th item at the $j$-th position generates utility $W_{ij}$. The utility of a ranking is the sum of utilities
generated by each item in its assigned position. The algorithmic task in the ranking problem is to
output a ranking with the highest utility. We denote rankings by assignment matrices $R \in \{0, 1\}^m \times n$,
where $R_{ij} = 1$ indicates that item $i$ appears in position $j$, and $R_{ij} = 0$ indicates otherwise. In this
notation, the utility of a ranking is $\langle R, W \rangle := \sum_{i=1}^{m} \sum_{j=1}^{n} R_{ij} W_{ij}$. Then this ranking problem is to
solve: $\max_{R \in \mathcal{R}} \langle R, W \rangle$. Where $\mathcal{R}$ is the set of all assignment matrices denoting a ranking:

$$\mathcal{R} := \left\{ X \in \{0, 1\}^{m \times n} : \forall i \in [m], \sum_{j=1}^{n} X_{ij} \leq 1, \forall j \in [n], \sum_{i=1}^{m} X_{ij} = 1 \right\}. \quad (1)$$
As a running example, we consider the fair-ranking problem with equal representation with two socially-salient groups $G_1, G_2, \ldots, G_p \subseteq [m]$ (e.g., the group of all women or all Black people) which are often protected by law. Each of the $m$ items belongs to one or more of these socially-salient groups (henceforth referred to as just groups). This fair-ranking problem is to output the ranking with maximum utility subject to satisfying certain fairness criteria with respect to these groups. The appropriate notion of fairness is context dependent, and to capture different fairness criteria numerous fairness constraints have been proposed. We consider a class of general fairness constraints.

**Definition 3.1 (Fairness constraints).** Given a matrix $U \in \mathbb{Z}_+^{n \times p}$, a ranking $R$ satisfies the upper bound constraint if $\sum_{i \in G_\ell} \sum_{j=1}^{k} R_{ij} \leq U_{k\ell}$, for all $\ell \in [p]$ and $k \in [n]$.

Existing works consider similar constraints and show that they can encapsulate a variety of fairness criteria [61]. For instance, when groups are disjoint, to capture equal and proportional representation, one can choose $U_{k\ell} := \left\lfloor \frac{k}{p} \right\rfloor$ and $U_{k\ell} := \left\lfloor \frac{k \cdot \rho \cdot \delta}{m} \right\rfloor$ for all $k$ and $\ell$ respectively. (That said, they do not capture qualitative differences among groups, such as, misrepresentation of demographics in image results [48], which could arise even when rankings have sufficient individuals from each group.)

As a running example, we consider the fair-ranking problem with equal representation with two disjoint groups, i.e.,

$$\max_{R \in \mathcal{R}} \langle R, W \rangle \quad \text{s.t.} \quad \forall k \in [n] \forall \ell \in [2], \quad \sum_{i \in G_\ell} \sum_{j=1}^{k} R_{ij} \leq \left\lceil \frac{k}{2} \right\rceil. \quad (2)$$

To ease readability, we omit ceilings-operators henceforth.

**Noise model.** If the socially-salient attributes of items are known accurately, then one can solve the fair-ranking problem. However, as discussed, in many contexts, attributes are inaccurate, missing, or only probabilistically known. Several models have been proposed to capture different errors in attributes. Here, we consider a model (due to [3]) which has also appeared in [25, 42, 48].

**Definition 3.2 (Noise model).** Let $P \in [0, 1]^{m \times p}$ be a known matrix. The groups $G_1, \ldots, G_p \subseteq [m]$ are random variables, such that, for each $i \in [m]$ and $\ell \in [p]$, $Pr[G_\ell \ni i] = P_{i\ell}$. Moreover, for different items $i \neq j$ the events $G_\ell \ni i$ and $G_k \ni j$ are independent for all $\ell, k \in [p]$.

Definition 3.2 makes two key assumptions: the matrix $P$ is known and for each item $i$, the events $G_\ell \ni i$ over groups $\ell$ are independent of the corresponding events for other items. Both of these hold when attributes are flipped to preserve local differential privacy (Remark A.1). In other settings, $P$’s estimate can be inaccurate and above events may be correlated. These can adversely affect the performance of our framework. We empirically study this in simulations where $P$ is estimated using confidence scores of off-the-shelf classifiers and is miscalibrated (Figures 2 and 3). Supplementary Material A shows how Definition 3.2 captures both disjoint and overlapping groups.

**Fairness constraint with noisy attributes.** Most existing fairness constraints assume that the groups are deterministic. Hence, it is not clear how to impose them when groups are random variables, as in Definition 3.2. One definition is to require the constraints to be approximately satisfied with high probability. Consider the instantiation of this definition for equal representation: A ranking $R$ satisfies $(\rho, \delta)$-equal representation, if with probability $1 - \delta$, at most $\left\lfloor \frac{k}{2} (1 + \rho) \right\rfloor$ items from $G_\ell$ appear in the first $k$ positions in $R$ places for all $k \in [n]$ and $\ell \in [p]$. Naturally, one would like to satisfy this definition for small $\delta, \rho$. However, it turns out to be too stringent and is infeasible for any small $\delta, \rho$.

**Proposition 3.3.** No ranking satisfies $(\rho, \delta)$-equal representation for $\rho < 1, \delta \leq \frac{1}{2}$, and $P = \left\lfloor \frac{1}{2} \right\rfloor$. The proof of Proposition 3.3 shows that any ranking $R$ violates the equal-representation constraint at the 2nd position by a multiplicative factor of 2 with probability $\frac{1}{2}$. The issue is that the same relaxation parameter $\rho$ is used for each position $k$ (whereas the information theoretically best-achievable relaxation parameter at $k$ increases as $k$ increases, this, e.g., follows by Theorem 4.1). Motivated by this observation, we consider the following alternate version of upper bound constraints.
Definition 3.4 ((ɛ, δ)-constraint). For any ɛ \in \mathbb{R}_{\geq 0}^n \text{ and } \delta \in (0, 1], a ranking } R \text{ is said to satisfy (ɛ, δ)-constraint if with probability at least } 1 - \delta \text{ over the draw of } G_1, \ldots, G_p

\forall k \in [n] \forall \ell \in [p], \sum_{i \in G_\ell} \sum_{j=1}^k R_{ij} \leq U_{k\ell} (1 + ɛ_k).

(3)

We would like to output a ranking that satisfies Definition 3.4 for small ɛ and small ɛ_1, ɛ_2, \ldots, ɛ_n.

Problem 3.5 (Ranking problem with noisy attributes). Given matrices } P, U, \text{ and } W, \text{ find the ranking } R \text{ maximizing utility } \langle R, W \rangle \text{ subject to satisfying (ɛ, δ)-constraint for some small ɛ and δ.}

3.1 Challenges in solving Problem 3.5

In this section we discuss potential approaches for solving Problem 3.5. In other words, solving:

\[
\max_{R \in \mathbb{R}} \langle R, W \rangle, \text{ s.t. } R \text{ satisfies (ɛ, δ)-constraint.}
\]

(4)

Even for two disjoint groups, given V, it is NP-hard to decide if the value of Program (4) is at least V (Theorem 5.12). To bypass this hardness, one can consider approximation algorithms. Program (4) is an integer program (IP) because the entries of the matrix } R \text{ are required to be integers (Equation (1)).}

A standard approach to (approximately) solve IPs is to: (1) consider their continuous relaxation that drops the integrality constraints, (2) compute the optimal solution } R_c \text{ of the relaxed problem, and then (3) “round” } R_c \text{ to satisfy integrality constraints while “retaining” its utility and fairness properties.}

To take this approach, we first need an efficient algorithm to find } R_c. \text{ However, not just Program (4), but even its continuous relaxation is non-convex. Hence, it is unclear how to solve it to find } R_c.

Due to the independence assumption in Definition 3.2, the number of items from } G_\ell \text{ appearing in the first } k \text{ positions of a ranking is concentrated around its expectation (for large } k). \text{ This implies that if, in expectation, less that } U_{k\ell} \text{ items from } G_\ell \text{ appear in the top } k \text{ positions then, with high probability, the number of items from } G_\ell \text{ in the top } k \text{ positions is not much larger than } U_{k\ell}. \text{ Using this one can show that a ranking satisfying the following constraints}

\[
\forall k \in [n] \forall \ell \in [p], \mathbb{E} \left[ \sum_{i \in G_\ell} \sum_{j=1}^k R_{ij} \right] \leq U_{k\ell}
\]

(5)

also satisfies (ɛ, δ)-constraint for small ɛ and δ. One idea is to find the ranking maximizing utility subject to satisfying Constraint (5). A feature of Constraint (5) is that it is linear in } R \text{ as } \mathbb{E}[\sum_{i \in G_\ell} \sum_{j=1}^k R_{ij}] = \sum_{i=1}^m \sum_{j=1}^k P_{ij} R_{ij} \text{ and, hence, one may hope to find the ranking with the maximum utility subject to satisfying Constraint (5). However, the issue is that there are examples where any ranking satisfying Constraint (5) has 0 utility and there are rankings that satisfy (ɛ, δ)-constraint and have a large positive utility (Lemma E.10). Hence, this approach can output rankings whose utility is significantly smaller than the utility of the solution to Problem 3.5. To overcome this, we relax Constraint (5) by a carefully chosen position-dependent factor, such that, any ranking satisfying the (ɛ, δ)-constraint (for appropriate ɛ and δ) is also feasible for our framework.

4 Theoretical results

In this section we present our optimization framework and its fairness and utility guarantees.

\begin{center}
\begin{tabular}{|c|c|c|}

\textbf{Input: Matrices } & \textbf{Our Fair-Ranking Program} \\
\hline
\textbf{Parameters: } & \textbf{max}_{R \in \mathbb{R}} \langle R, W \rangle, \text{ (Noise Resilient) (7)} \\
\textbf{Constant } c > 1, \text{ failure probability } & \text{ s.t. } \forall \ell \in [p] \forall k \in [n] \\
\textbf{δ ∈ (0, 1], and } k \in [n], \text{ relaxation parameter } & \sum_{i \in [m], j \in [k]} P_{ij} R_{ij} \leq U_{k\ell} \left( 1 + \left( 1 - \frac{1}{2\sqrt{c}} \right) \gamma_k \right). \text{ (8)} \\
\textbf{γ_k := 12 \cdot \log (\frac{2\sqrt{c}}{\delta}) \cdot max}_{i \in [p]} \sqrt{\frac{1}{U_{k\ell}}}. \text{ (6)}} \\
\hline
\end{tabular}
\end{center}

The above program modifies the program for fair ranking with accurate groups: It has the same objective but different constraints. Instead of sampling the attribute values and applying constraints on the sampled values, Constraint (6) applies upper bounds on the expected number of items in the first } k \text{ positions from group } \ell \text{ (Section 3.1). Further, Constraint (7) relaxes upper bounds } U_{k\ell} \text{ by a small position-dependent factor. Like for Constraint (5), one can show that any ranking satisfying Constraint (6) also satisfies (ɛ, δ)-constraint (for small ɛ_1, \ldots, ɛ_n and δ). But unlike Constraint (5),}
and somewhat surprisingly, any ranking that satisfies \((\varepsilon, \delta)\)-constraint (for appropriate \(\varepsilon_1, \ldots, \varepsilon_n\) and \(\delta\)) must also satisfy Constraint (8). (In fact, \(\gamma_k\) is chosen to be the smallest, up to logarithmic factors, value such that this is true.) We use this to prove Theorem 4.1’s utility guarantee.

Our first result bounds the fairness and utility of the optimal solution of Program (7).

**Theorem 4.1.** Let \(\gamma \in \mathbb{R}^n\) be as defined in Equation (6). There is an optimization program (Program (7)), parameterized by a constant \(c\) and failure probability \(\delta\), such that for any \(c > 1\) and \(\delta \in (0, \frac{3}{4})\) its optimal solution satisfies \((c\gamma, \delta)\)-constraint and has a utility at least as large as the utility of any ranking satisfying \((c - \sqrt{c})\gamma, \delta)\)-constraint.

For equal representation, \(\gamma_k\) is \(\tilde{O}\left(\frac{1}{\sqrt{k}}\right)\). Thus, Theorem 4.1 guarantees that, with high probability, the optimal solution of Program (7) multiplicatively violates equal representation at the \(k\)-th position by at most \(1 + \tilde{O}\left(\frac{1}{\sqrt{k}}\right)\). Further, this solution’s utility is higher than the utility of any ranking satisfying a slight relaxation of this fairness guarantee. Theorem 4.1 can be extended to position-weighted versions of fairness constraints (Theorem F.1), where the fairness constraint is \(\sum_{i \in G_k} \sum_{j \in [k]} R_{ij} \leq U_{ke}\) (for all \(k\) and \(\ell\)) for specified discount factors \(v_1 \geq \cdots \geq v_n\) such as NDCG [33]. If we are also guaranteed \(U_{ke} \geq \psi k\) for some constant \(\psi > 0\) and all \(k\) and \(\ell\), then we can improve \(\gamma_k\)’s dependence on \(\delta\) from \(\log \frac{1}{\delta} \) to \(\sqrt{\log \frac{1}{\delta}}\) (Supplementary Material E.3). The proof of Theorem 4.1 appears in Section 6.

**Lower bound on fairness guarantee.** Our next result complements Theorem 4.1’s fairness guarantee.

**Theorem 4.2.** There is a family of matrices \(U \in \mathbb{Z}_+^{n \times p}\) such that for any \(U\) in the family and any parameters \(\delta \in (0, 1)\) and \(\varepsilon_1, \ldots, \varepsilon_n \geq 0\), if for any position \(k \in [n]\), \(\varepsilon_k \leq 1\) and \(\varepsilon_k < \max_{\ell \in [p]} \sqrt{\frac{1}{(2\pi k)} \log \frac{1}{\delta}}\) then there exists a matrix \(P \in [0, 1]^{m \times p}\), such that it is information theoretically impossible to output a ranking that satisfies \((\varepsilon, \delta)\)-constraint. This family, in particular, contains the matrices \(U\) corresponding to equal representation and proportional representation constraints.

Since \(\gamma_k = O\left(\log(\frac{m}{\varepsilon_p}) \cdot \max_{\ell \in [p]} \sqrt{\frac{1}{(2\pi k)} \log \frac{1}{\delta}}\right)\), Theorem 4.2 shows that Theorem 4.1’s fairness guarantee is optimal up to log-factors. Supplementary Material D.1 proves Theorem 4.2.

**An efficient algorithm.** As for solving our optimization program, it is NP-hard to check its feasibility (Theorem E.7). However, because Constraint (8) is linear in \(R\), the continuous relaxation of Program (7) is a standard linear program and can be solved efficiently. Our algorithm (Algorithm 1) solves the standard linear programming relaxation of Program (7) to find a solution \(R_c\) and then uses a dependent-rounding algorithm by [19] to convert \(R_c\) to a ranking. (See Supplementary Material D.2 for brief discussion of why straightforward rounding approaches are insufficient.)

**Theorem 4.3.** There is a randomized algorithm (Algorithm 7) that given constants \(d > 2\), a failure probability \(0 < \delta < 1\), and matrices \(P \in [0, 1]^{m \times p}\) and \(W \in [0, 1]^{m \times n}\) outputs a ranking satisfying \((O(d\gamma), \delta)\)-constraint and with probability at least \(1 - \delta\), and has a utility at least \((1 - \frac{1}{2}) \cdot V - \tilde{O}(\sqrt{dn})\), where \(V\) is the utility of any ranking satisfying \(((d - \sqrt{d})\gamma, \delta)\)-constraint. The algorithm runs in polynomial time in \(d\) and the bit complexity of the input.

The tension in setting \(d\) is that decreasing \(d\) improves the fairness guarantee and the utility guarantee’s second term, but worsens the first term in the utility guarantee. Under the mild assumption that \(V = \Omega(n)\), increasing \(d\) improves the utility guarantee because the first term in the utility guarantee dominates the second term. In this case, the utility guarantee improves to \((1 - \frac{1}{2} - O(1)) \cdot V\). Finally, while Theorem 4.3 requires utilities to be between 0 and 1, it can be extended to any non-negative and bounded utilities by scaling. The proof of Theorem 4.3 appears in Supplementary Material D.2.

5 Empirical results

In this section we evaluate our framework’s performance on synthetic and real-world data.

**Baselines and metrics.** The correct choice of fairness metric is context-dependent and beyond the scope of this work [60]. To illustrate our results, we arbitrarily fix the fairness metric as weighted

---

1 The bit complexity of the inputs is the number of bits required to encode the input using the standard binary encoding (which, e.g., maps integers to their binary representation, rational numbers as pair of integers, and vectors/matrices as a tuple of their entries) [31] Section 1.3.
2 Code for our simulations is available at [https://github.com/AnayMehrotra/FairRankingWithNoisyAttributes](https://github.com/AnayMehrotra/FairRankingWithNoisyAttributes)
risk-difference (RD). This is a position-weighted version of the standard risk-difference metric \cite{13} and measures the extent to which a ranking violates equal representation. The RD of a ranking \( R \) is:

\[
1 - \frac{1}{Z} \sum_{k=5,10,\ldots} \frac{1}{\log k} \max_{q \in [p]} \left| \sum_{i \in G_k, j \in [k]} R_{ij} - \sum_{i \in G_q, j \in [k]} R_{ij} \right|
\]

where \( G \) denotes the ground-truth protected groups and \( Z \) is a constant so that RD has range \([0, 1]\). Here, \( \text{RD} = 1 \) is most fair and \( \text{RD} = 0 \) is least fair. We compare our framework, NResilient, against state-of-the-art fair-ranking algorithms: CSV ("greedy" in \cite{18}), SJ \cite{61}, and GAK ("Det-Greedy" in \cite{27}). We also compare against MC, which ranks the items, in the subset output by \cite{48}'s algorithm, to maximize utility. Finally, we compare against the baseline, Uncons, which outputs the utility maximizing ranking without fairness considerations. We present additional discussion of baselines and results, additional plots for RD, and comparisons with weighted selection-lift (instead of RD) and different choices of \( U \) (than the ones below) in Supplementary Material\[C\].

**Setup.** We consider the DCG model of utilities \cite{33} and a relaxation of equal representation constraints: (1) Given an intrinsic value \( w_i \geq 0 \) for each item \( i \), we set \( w_{ij} := w_i \left( \log (j + 1) \right)^{-1} \) for each \( i \in [n] \). (2) Given a parameter \( \phi \in [1, p] \), we set upper bounds \( U_{k\ell} := \frac{\phi}{p} \cdot k \) for each \( k \in [n] \) and \( \ell \in [p] \). In simulations, we set \( m = 500 \), \( n = 25 \), and vary \( \phi \) from \( p \) to \( 1 \). To gain some intuition about the relevant values of \( \phi \), note that satisfying the 80% rule requires \( \phi \leq \frac{5\phi}{4G - 1} \), i.e., \( \phi \leq 1.11 \) for \( p = 2 \) and \( \phi \leq 1.05 \) for \( p = 4 \). For each \( \phi \), we draw \( m \) items uniformly without replacement and compute an estimate \( \hat{P} \) of the matrix \( P \) (from Definition 3.2) using, e.g., off-the-shelf ML classifiers or public APIs (see the paragraphs "Estimating \( \hat{P} \)" in simulation with image data and "Setup" in simulation on name data). We infer socially-salient groups \( G_1, \ldots, G_p \) via \( P \) by assigning each item to its most-likely group. Finally, we run all algorithms using \( P \) or \( G_1, \ldots, G_p \), as discussed next.

**Implementation details.** NResilient and MC take probabilistic information about socially-salient attributes as input and are given \( P \). CSV, SJ, and GAK require access to socially-salient groups and are given \( G_1, \ldots, G_p \). NResilient, SJ, and CSV use fairness constraints from Definition 3.1 and are given: for each \( k \) and \( \ell \), \( U_{k\ell} = \frac{\phi}{p} \cdot k \). MC requires, for each \( \ell \in [p] \), an upper bound on the number of items from \( G_\ell \) that can appear in top-\( n \) positions. It is given \( \frac{\phi}{p} \cdot n \) for each \( \ell \in [p] \). GAK requires the desired proportion \( \alpha_\ell \) for each group \( G_\ell \) and, roughly, satisfies the constraint \( U_{k\ell} = \alpha_\ell \cdot k \) for each \( k \in [n] \) and \( \ell \in [p] \). It is given \( \alpha_\ell = \frac{\phi}{p} \) for each \( \ell \in [p] \), this corresponds to \( \phi = 1 \) (hence, figures only plot the GAK at \( \phi = 1 \)). As a heuristic, we set \( \gamma_\ell = \frac{1}{29} \max_{j \in [p]} \sqrt{U_{k\ell}} \) in all simulations. We find that this suffices and expect a more refined approach to improve the performance of NResilient.

**5.1 Simulation on synthetic data**

We show that on synthetic data, where error-rates of given socially-salient attributes vary over groups, existing fair-ranking algorithms have worse RD than Uncons.

**Data.** We generate \( w \) and \( P \) for two groups using code by \cite{48} and fix \( \hat{P} = P \). For all items \( i \), \( w_i \) is i.i.d. from the uniform distribution over \([0, 1] \). \( \hat{P} \) is constructed such that attributes inferred from \( P \) have a higher false-discovery rate for the minority group compared to the majority (40% vs 10%)\[3\].

---

\[3\]This 30% difference in false-discovery rates is comparable to the 34% difference in the false-discovery rates of dark-skinned females and light-skinned men observed by \cite{10} for a commercial classifier.
We consider gender and race (encoded as binary) as socially-salient attributes. Our goal is to ensure (apparent) gender of the person depicted in each image. We calibrate the confidence scores output (41/96 occupations). An image is said to be stereotypical if it is in a gender-stereotypical occupation and its gender label is the majority label for its occupation. We define the socially-salient groups as non-men, White non-men, non-White men, and White men.

**Setup.** For each image \(i\), with rank \(r_i\), we define \(w_i := (\log(1 + r_i))^{-1}\). We say an occupation is gender-stereotypical if more than 80% of the images for this occupation have the same gender label (41/96 occupations). An image is said to be stereotypical if it is in a gender-stereotypical occupation and its gender label is the majority label for its occupation. We define the socially-salient groups as the sets of stereotypical and non-stereotypical images in gender-stereotypical occupations.

**Estimating \(\hat{P}\).** After pre-processing, we use a CNN-based gender-classifier \(f\) [59] to predict the (apparent) gender of the person depicted in each image. We calibrate the confidence scores output by \(f\) by binning and use these to estimate \(\hat{P}\) (see Supplementary Material [G] for more details). We perform this calibration once and on all occupations and, then, use it for gender-stereotypical occupations. Because of this \(\hat{P}\) is miscalibrated (and hence, inaccurate). For instance, among samples \(i\) for which \(0.25 \leq P_{i,\text{male}} \leq 0.5\), more than 75% are labeled as ‘man’ (instead of some percentage between 25% and 50%). *This violates the assumption that \(P\) is accurately known.*

**Results.** See Figure [4] for the observed RD averaged over 1000 iterations. We observe that NResilient achieves best RD (≈0.81) and has a better RD-utility trade-off than the other baselines. In contrast, CSV, SJ, and GAK, achieve a worse RD (≤0.77), but do not provide them to algorithms. This value of RD can arise in practice: Figure 9 plots the RD-utility trade-off. Error bars show the error of the mean.

### 5.2 Simulation on real-world image data

In this simulation, given *non-gender labeled* images-search results and their utilities, our goal is to generate a high-utility and gender-balanced ranking.

**Data.** We use the Occupations dataset [15] which contains the top 100 Google Image results for 96 occupation-related queries. For each image, the data has its position in search results, gender (coded as male/female) of the individual depicted in the image, collected via MTurk. We use the (true) gender labels in the data to compute RD and to estimate \(\hat{P}\), but do not provide them to algorithms.

**Setup.** For each image \(i\), with rank \(r_i\), we define \(w_i := (\log(1 + r_i))^{-1}\). We say an occupation is gender-stereotypical if more than 80% of the images for this occupation have the same gender label (41/96 occupations). An image is said to be stereotypical if it is in a gender-stereotypical occupation and its gender label is the majority label for its occupation. We define the socially-salient groups as the sets of stereotypical and non-stereotypical images in gender-stereotypical occupations.

**Estimating \(\hat{P}\).** After pre-processing, we use a CNN-based gender-classifier \(f\) [59] to predict the (apparent) gender of the person depicted in each image. We calibrate the confidence scores output by \(f\) by binning and use these to estimate \(\hat{P}\) (see Supplementary Material [G] for more details). We perform this calibration once and on all occupations and, then, use it for gender-stereotypical occupations. Because of this \(\hat{P}\) is miscalibrated (and hence, inaccurate). For instance, among samples \(i\) for which \(0.25 \leq P_{i,\text{male}} \leq 0.5\), more than 75% are labeled as ‘man’ (instead of some percentage between 25% and 50%). *This violates the assumption that \(P\) is accurately known.*

**Results.** See Figure [4] for RD and utilities (NDCG) averaged over 1000 iterations. We observe that NResilient achieves the best RD (≈0.81) and has a better RD-utility trade-off than the other baselines. In contrast, CSV, SJ, and GAK, achieve a worse RD (≤0.77). NResilient achieves the worst RD (≤0.70) and a worst RD-utility trade-off. In particular, NResilient’s RD-utility trade-off strictly dominates all baselines for RD ≥ 0.66. This value of RD can arise in practice: Figure 9 plots the RD vs \(\phi\) for this simulation and shows that if \(\phi \leq 1.1\) (as required to, e.g., guarantee satisfaction of the 80% rule), then all baselines have RD at least 0.66. We further evaluate the robustness of NResilient to varying levels of noise on the Occupations dataset in Supplementary Material [G] and observe NResilient has a better or similar RD than all baseline at all noise levels.

### 5.3 Simulation on real-world name data

We consider gender and race (encoded as binary) as socially-salient attributes. Our goal is to ensure equal representation across the four disjoint groups formed by combinations of these: non-White non-men, White non-men, non-White men, and White men.

**Data.** We consider the chess ranking data [29] which has of 3,251 chess players. For each player, among other attributes, the data has their full-name, self-identified gender (coded as male/female),
FIDE rating, and race (Asian, Black, Hispanic, White) collected via MTurk. We use the (true) gender and race labels in the data to evaluate RD, but do not provide them to algorithms.

**Setup.** We partition the races into White (81.66%) and non-White (18.34%). For each player $i$, we query Genderize and EthniCol with $i$’s full-name to obtain the “probabilities” $p_f(i)$ and $p_{nw}(i)$ that player $i$ is labeled as a women and non-white respectively. We assume that these probabilities are correct and that the gender and race of players are drawn independently. Hence, e.g., we set the probability that $i$ is a non-white women as $P_{i,nw+f} = p_{nw}(i) p_f(i)$. Similarly, we set $P_{i,nw+f} = (1 - p_{nw}(i)) p_f(i)$, and $P_{i,nw+f} = (1 - p_{nw}(i))(1 - p_f(i))$.

Notably, we do not calibrate $P$ on this data. We verify that, like the previous simulation, $P$ is miscalibrated in this simulation. E.g., only 31% of the samples $i$ for which $P_{i,nw+f} > 0.75$ are labeled as ‘Non-white man’ (instead of 75%). Hence, the assumption that $P$ is accurately known is violated in this simulation. We expect calibration to improve NResilient’s performance.

**Results.** See Figure 3 for RD averaged over 500 iterations. We observe that all algorithms (NResilient, CSV, GAK, SJ, and MC) have better RD than Uncons. Among these, NResilient achieves the best RD ($≈ 0.67$), next CSV, GAK, and SJ obtain RD ($≈ 0.61$), and MC achieves RD ($≤ 0.53$). More specifically, for all $\phi ≤ 1.75$, NResilient has a strictly better RD than all baselines (this range of $\phi$ subsumes, e.g., the range $\phi ≤ 1.05$-required guarantee satisfaction of the 80% rule with four groups.) Further, in Figure 10, we observe that all algorithms have a similar fairness-utility trade-off.

### 6 Proof of Theorem 4.1

In this section we prove Theorem 4.1. Some of the details are deferred to Supplementary Material E.3 due to space constraints. The proof is divided into two propositions:

**Proposition 6.1.** For any $\delta \in (0, 1]$, any ranking feasible for Program (7) satisfies $(c\gamma, \delta)$-constraint.

**Proposition 6.2.** For any $\delta \in (0, 1/2)$ and $c > 1$, any ranking satisfying the $(\gamma + \sqrt{\gamma} \delta, \delta)$-constraint is feasible for Program (7).

**Proof of Theorem 4.1** Let $R^*$ be the optimal solution of Program (7). Since $R^*$ is feasible by definition, Proposition 6.1 implies that $R^*$ satisfies the $(c\gamma, \delta)$-constraint. Pick any $R'$ that satisfies the $(\gamma + \sqrt{\gamma} \delta, \delta)$-constraint. Proposition 6.2 implies that $R'$ is feasible for Program (7). Since $R^*$ is an optimal solution of Program (7), $R^*$’s utility is at least as large as the utility of $R'$. □

**Notation.** For each item $i$ and group $\ell$, let $Z_{i,\ell} \in \{0, 1\}$ be the indicator random variable $Z_i := \mathbb{I}[G_{i,\ell} \ni i]$. By Definition 3.2, $\Pr[Z_{i,\ell} = P_\ell] = P_\ell$ and $Z_{i,\ell}$ and $Z_{j,\ell}$ are independent for any $i \neq j$. Given ranking $R \in \mathcal{R}$, group $\ell \in [p]$, and position $k \in [n]$, let $Z_{\#,\ell}(R, \ell, k)$ be the number of items from $G_{\ell}$ in the top $k$ positions of $R$ and let $P_\#(R, \ell, k) = \mathbb{E}[Z_{\#,\ell}(R, \ell, k)]$. From the above, we get:

$$P_\#(R, \ell, k) = \mathbb{E}[Z_{\#,\ell}(R, \ell, k)] = \sum_{i \in [m]} \sum_{j \in [k]} P_{ij} R_{ij}.$$

We use the following concentration result (proved in Supplementary Material E.2) in the proof.

**Lemma 6.3.** For any position $k \in [n]$, group $\ell \in [p]$, parameters $\varepsilon \geq 0$ and $L, U \in \mathbb{R}$, and ranking $R \in \mathcal{R}$, where $R$ is possibly a random variable independent of $\{Z_{i,\ell}\}_{i,\ell}$ if $F_\#(R, \ell, k) \leq U$ or

\[ \text{gender-api.com and github.com/appeler/ethnicolr respectively} \]

---

**Figure 3: Real-World Name Data: Multiple Attributes.** In this simulation, the goal is to ensure equal representation across four disjoint groups formed by combinations of two attributes (non-White non-men, White non-men, non-White men, and White men). We estimate $P$ by querying public APIs and libraries with names in the data. The $y$-axis plots RD and $x$-axis plots $\phi$. *Note that the values decrease toward the right.* We observe that all algorithms have a better RD than Uncons and NResilient has the best RD compared to all other baselines. Error bars represent the error of the mean.
\[ P_\#(R, \ell, k) \geq L \text{ then the following equations hold respectively } \Pr[Z_\#(R, \ell, k) < (1 + \epsilon) U] \geq 1 - e^{-\frac{\gamma_k^2}{2np}} \text{ and } \Pr[Z_\#(R, \ell, k) > (1 - \epsilon) L] \geq 1 - e^{-\frac{c^2\gamma_k^2}{4np}}. \]

**Proof of Proposition 6.1** Fix any \( k \) and \( \ell \). Let \( \phi := 1 - \frac{1}{2\epsilon} \), \( U' := U_{k\ell}(1 + \phi \gamma_k) \), and \( \zeta := \frac{(1 - \phi) \gamma_k}{1 + \phi \gamma_k}. \) Here, \( U' \) and \( \zeta \) satisfy \( U'(1 + \zeta) = U_{k\ell}(1 + c\gamma_k) \). Fix any ranking \( R \) that is feasible for Program (7). Since \( R \) is feasible, it satisfies that
\[ \forall \ell \in [p], k \in [n], \quad P_\#(R, \ell, k) \leq U_{k\ell}(1 + \phi \gamma_k). \] (10)

Using \( U'(1 + \zeta) = U_{k\ell}(1 + c\gamma_k) \), Equation (10), and Lemma 6.3, we get that
\[ \Pr[Z_\#(R, \ell, k) \geq U'(1 + \zeta)] \leq e^{\frac{-2c^2\gamma_k^2}{2np}} \leq e^{-\frac{(1-\phi)^2\gamma_k^2U_{k\ell}}{2np}} (\phi \leq 1) \leq e^{-\frac{(1-\phi)^2\gamma_k^2U_{k\ell}}{2np}}. \] (11)

**Fact 6.4.** For all \( x, y \geq 0 \), if \( x \geq y + \sqrt{y} \), then \( \frac{x^2}{1+x} \geq y. \)

Using Fact 6.4 and Equation (11), we can show that for each \( k \), \( c^2\gamma_k^2 \geq \frac{2U_{k\ell}}{(1-\phi)^2}\log\frac{2np}{\delta}. \) (This uses \( \delta < \frac{1}{2} \) and \( U_{k\ell}, n \geq 1 \).) Substituting this in Equation (11) we get:
\[ \Pr[Z_\#(R, \ell, k) \geq U_{k\ell}(1 + c\gamma_k)] \leq \frac{\delta}{2np}. \] (12)

Taking the union bound over all positions \( k \) and \( \ell \), we get (as desired) that with probability at least \( 1 - \delta \), for all \( k \in [n] \) and \( \ell \in [p] \), \( Z_\#(R, \ell, k) \leq U_{k\ell}(1 + c\gamma_k). \) \( \square \)

**Proof of Proposition 6.2** Let \( \phi := 1 - \frac{1}{\sqrt{\epsilon}} \). Towards a contradiction, suppose that \( R' \) satisfies \((c - \sqrt{\epsilon})\gamma, \delta\)-constraint but is not feasible for Program (7). Then there exists \( \ell \) and \( k \) such that \( P_\#(R', k, \ell) > U_{k\ell} \cdot (1 + \phi \gamma_k) \). Fix any \( k \) and \( \ell \) satisfying this. Let \( b := 1 - \frac{1}{\sqrt{\epsilon}} \), \( L' := U_{k\ell}(1 + \phi \gamma_k) \) and \( \zeta := \frac{(1+b)\gamma_k}{1+\phi \gamma_k}. \) (13)

It holds that \( L'(1-\zeta) = U_{k\ell}(1+b\gamma_k) \), and, hence, we get
\[ \Pr[Z_\#(R', k, \ell) \leq L'(1-\zeta)] \leq e^{\frac{-c^2\gamma_k^2}{2np}} \leq e^{-\frac{(c-b)^2U_{k\ell} \gamma_k}{2np}} \leq e^{-\frac{U_{k\ell}(1+b\gamma_k)}{2np}}. \] (14)

Since \( \gamma_k \geq 8 \log \frac{np}{\delta} \cdot \max_{\ell} \sqrt{\frac{1}{\ell^2}} \cdot \delta < \frac{1}{2} \), and \( U \geq 1 \), we have \( \Pr[Z_\#(R', k, \ell) \leq U_{k\ell}] \leq \frac{\delta}{np} < 1 - \delta \). Since \( R' \) satisfies \((c - \sqrt{\epsilon})\gamma, \delta\)-constraint we have a contradiction, hence \( R' \) must be feasible. \( \square \)

### 7 Limitations and conclusions

Recent studies find that errors in socially-salient attributes can adversely affect fairness and utility of existing fair-ranking algorithms [29]. We consider a model of random and independent errors in socially-salient attributes and present a framework that can output rankings with high fairness and utility in this model. This framework works for a general class of fairness criteria, which involves multiple overlapping groups and upper bounds on the number of items that appear in the first \( k \) positions from each group. We also show near-tightness of the framework’s fairness guarantee. Empirically, on both synthetic and real-world datasets, we observe that, compared to baselines, our framework can achieve higher fairness-values and a similar or better fairness-utility trade-off for standard metrics.

Compared to existing fair-ranking frameworks, our framework does not need accurate socially-salient attributes, but assumes that errors in attributes are random and independent. These assumptions do not hold, our framework may not satisfy its guarantees and a careful assessment of this on application-specific data would be important to avoid any (unintended) negative social impact.

Our work only addresses one aspect of how bias may show up in rankings, and more generally, on the web. For instance, while we consider a large class of fairness constraints, it does not capture some important notions such as the qualitative representation of different groups [38, 55]. It is important to take an holistic approach to mitigate bias and incorporate our work as a part of such a broader effort. Finally, our work adds to the line of works that develop fair decision-making algorithms robust to inaccuracies in data [42, 6, 54, 23, 67, 66, 48, 14].

Checklist

1. For all authors...
   (a) Do the main claims made in the abstract and introduction accurately reflect the paper’s contributions and scope? [Yes] See the theorems in Section 4 and Figures 1 to 3
   (b) Did you describe the limitations of your work? [Yes] See Section 7
   (c) Did you discuss any potential negative societal impacts of your work? [Yes] Section 7 discusses the importance of assessing the performance of our algorithm on application-specific data and using it as a part of a larger framework for mitigating discrimination.
   (d) Have you read the ethics review guidelines and ensured that your paper conforms to them? [Yes]

2. If you are including theoretical results...
   (a) Did you state the full set of assumptions of all theoretical results? [Yes] See, e.g., Theorems 4.1 to 4.3 and F.1
   (b) Did you include complete proofs of all theoretical results? [Yes] See Supplementary Materials D to E

3. If you ran experiments...
   (a) Did you include the code, data, and instructions needed to reproduce the main experimental results (either in the supplemental material or as a URL)? [Yes] Code for our simulations is available at https://github.com/AnayMehrotra/FairRankingWithNoisyAttributes
   (b) Did you specify all the training details (e.g., data splits, hyperparameters, how they were chosen)? [Yes] See Supplementary Material G
   (c) Did you report error bars (e.g., with respect to the random seed after running experiments multiple times)? [Yes] Please see, e.g., Figures 1 to 3
   (d) Did you include the total amount of compute and the type of resources used (e.g., type of GPUs, internal cluster, or cloud provider)? [Yes] See Supplementary Material G

4. If you are using existing assets (e.g., code, data, models) or curating/releasing new assets...
   (a) If your work uses existing assets, did you cite the creators? [Yes] See Section 5
   (b) Did you mention the license of the assets? [N/A] We use existing code by [48] and data by [15, 29]. To the best of our knowledge these assets are not licensed.
   (c) Did you include any new assets either in the supplemental material or as a URL? [No]
   (d) Did you discuss whether and how consent was obtained from people whose data you’re using/curating? [N/A]
   (e) Did you discuss whether the data you are using/curating contains personally identifiable information or offensive content? [N/A]

5. If you used crowdsourcing or conducted research with human subjects...
   (a) Did you include the full text of instructions given to participants and screenshots, if applicable? [N/A]
   (b) Did you describe any potential participant risks, with links to Institutional Review Board (IRB) approvals, if applicable? [N/A]
   (c) Did you include the estimated hourly wage paid to participants and the total amount spent on participant compensation? [N/A]
G.1 Implementation details .................................................. 43
G.2 Further discussion and plots for simulations from Section 5 ............. 45
G.3 Additional empirical results .............................................. 47
A Further discussion on applicability of the noise model

The noise in Definition 3.2 arises in real-world settings where local differential privacy is ensured e.g., using the randomized response mechanism.

Remark A.1 (Model’s assumptions hold if attributes are perturbed by randomized response). The randomized response mechanism flips each item’s protected attribute to an incorrect value with some (public) probability $0 < \eta < \frac{1}{2}$, independent of all other items. Here, the independence assumption holds (by design) and $P$’s entries can be deduced from $\eta$. To see the latter concretely, consider two protected groups $G_1$ and $G_2$ ($p = 2$), and their noisy versions $N_1$ and $N_2$ corresponding to the “flipped” attributes. For any item $i \in N_1$, 

$$P_{11} = (1 - \eta) \cdot \frac{|G_1|}{|N_1|} \quad \text{and} \quad P_{21} = 1 - P_{11}.$$ 

For items in $N_2$, replace $P_{11}, P_{21}, G_1,$ and $N_1$ with $P_{21}, P_{11}, G_2,$ and $N_2$. When there are more than two groups ($p > 2$), then the randomized response mechanism publicly specifies the probability $\eta_{a,b}$ with which it flips protected attribute value $\ell = a$ to another value $\ell = b$ (for any $a, b \in [p]$). As in the binary case above, $P$’s entries can be deduced from parameters $\{\eta_{a,b}: a, b \in [p]\}$.

Further, in other real-world settings such as image search and online recruiting, the entries of $P$ can be estimated using the confidence scores of classifiers or using auxiliary attributes. In more detail:

- If the protected attribute is skin tone, then a classifier $C$ can be used to predict if image $i$ contains a person with a dark skin tone. If $C$ has a calibrated confidence score $0 \leq c(i) \leq 1$ in this prediction, then $P_{i,\text{darkskin}} = c(i)$. See Figure 2 in Section 5 for results from a simulation that estimates $P$ in this fashion.
- If the protected attribute is race and individuals are uniformly drawn from the population, then for an individual $i$ with surname $S$ and zip-code $Z$, $P_{i,S,L} = f(Z, S)$, where $f(Z, S)$ is the fraction of individuals with surname $S$ in zip-code $Z$ who have the $L$-th race; which can be estimated using census data [23] (see Figure 3 in Section 5).

Discussion on the noise model with disjoint groups vs. overlapping groups. For each item $i$ and group $G_\ell$ ($\ell \in [p]$), the noise model specifies the marginal probability that $i$ belongs to $G_\ell$:

$$P_{i,\ell} := \Pr[G_\ell \ni i].$$

For any $i$, the model allows for any joint probability distribution over the events

$$(G_1 \ni i), (G_2 \ni i), \ldots, (G_p \ni i)$$

that is consistent with the above marginal probabilities. This allows the model to capture the setting where all groups are disjoint – by requiring the events

$$(G_1 \ni i), \ldots, (G_p \ni i)$$

to be mutually exclusive. It also allows the model to capture the cases where all or only some of the groups can overlap. For instance, the case where $G_1$ can overlap with $G_2$ but both $G_1$ and $G_2$ are disjoint from $G_3$ can be captured by requiring the events $(G_3 \ni i)$ to be mutually exclusive of the events $(G_1 \ni i)$ and $(G_2 \ni i)$. Importantly, we do not need additional information to capture these settings–it suffices to know the marginal probabilities specified by $P$.

B Other related work on fair decision making with inaccuracies in attributes

Several recent works develop fair algorithms for tasks different from ranking that are robust to inaccuracies in the socially-salient attributes [42, 6, 54, 25, 67, 48, 60, 14, 17, 25]. In particular, several works study classification and clustering [42, 6, 54, 25, 67, 48, 66, 14, 17, 25], and develop fair algorithms robust to inaccuracies in protected attributes. Many of these works consider the same random error model as us (or one of its variants) [42, 6, 67, 48, 14, 25], but some very recent works have also considered adversarial noises in protected attributes [67, 41, 17]. However, because the
underlying algorithmic tasks are fundamentally different from the variant of the ranking problem we study it is not clear how to adapt their approaches to our setting. [48] studies the problem of fair subset selection under the same noise model. In subset selection, given \( m \) items the goal is to output an unordered subset of \( n \leq m \) items with the highest utility. They develop an optimization framework outputs a subset satisfying the fairness constraint up to a small multiplicative error with high probability but leave the problem of ranking open. We compare against an adaptation of their approach, MC, to ranking in our empirical results.

\section*{C Existing fair-ranking algorithms with rounding is insufficient}

Since existing fair-ranking algorithms require access to protected attributes, one way to use them under the above model is to imputed groups \( G_1, \ldots, G_p \) using the specified probabilities. Then run these algorithms w.r.t. the imputed groups. To see an illustration, consider two groups \( G_1 \) and \( G_2 \). A natural imputation strategy is to use the Bayes optimal classifier, which assigns item \( i \) to \( G_1 \) if and only if \( P_{G_1} > 0.5 \) and has the lowest expected imputation error. This may be reasonable when the imputation error is negligible. However, on exploring this strategy with non-negligible imputation error, we find that the output rankings can violate equal representation significantly (see Proposition C.2). To gain some intuition consider an extreme case where all items in some set \( S \), of size \( n \), have \( P_{G_1} = 0.51 \). The Bayes classifier assigns all items in \( S \) to \( G_1 \), i.e.,

\[ |S \cap \hat{G}_1| = |S|. \]

However, with high probability,

\[ |S \cap G_1| \approx 0.51 |S|. \]

Since \( |S \cap G_1| \) and \( |S \cap \hat{G}_1| \) are far, a ranking that selects \( n \) items from \( S \) and satisfies the constraints for \( \hat{G}_1 \) and \( \hat{G}_2 \) but violate constraints with respect to the true groups. Proposition C.1 gives an example where this occurs.

Another imputation strategy, is independent rounding: it assigns each item \( i \) to \( \hat{G}_1 \) with probability \( P_{G_1} \) and otherwise to \( G_1 \). This addresses the issue with Bayes imputation, because, it has property that for any set \( T \) of size \( n \), \( |T \cap \hat{G}_1| \) are close with probability \( 1 - e^{51(n)} \). However, when \( m \gg n \), there are

\[ \binom{m}{n} \gg e^n \]

sets of size \( n \), and hence, with high probability, there exists a set \( S \) of size \( n \) for which \( |S \cap \hat{G}_1| \) and \( |S \cap G_1| \) are arbitrarily far. In this case also, existing fair-ranking algorithms can output rankings which violate equal representation significantly. Proposition C.2 gives an example where this occurs.

**Proposition C.1 (Imputing protected groups using the bayes optimal classifier is not sufficient).** Let \( R \) be any optimal solution to (2) with protected groups imputed using the Bayes optimal classifier for given \( p \). There exists a matrix \( P \in [0,1]^{m \times 2} \) such that \( R \) does not satisfy the \((\varepsilon, \delta)\)-equal representation constraint

\[ \text{for any } \delta < \frac{1}{2} \text{ and } \varepsilon \text{ s.t. } \varepsilon_k < \frac{1}{20} \text{ for some } k \geq 2. \]

**Proposition C.2.** Let \( R \) be a random variable denoting the optimal solution to the fair-ranking problem (Program (2)) for protected groups imputed using independent rounding with given \( P \in [0,1]^{m \times 2} \). For every \( \beta > 0 \), there exists sufficiently large \( n \) and \( m \) and a matrix \( P \in [0,1]^{m \times 2} \), such that, with probability at least \( 1 - \beta \) \( R \) does not satisfy the \((\varepsilon, \delta)\)-equal representation constraint

\[ \text{for any } \delta < 1 - \beta \text{ and } \varepsilon \in (0,1)^n. \]

\subsection*{C.1 Proof of Proposition C.1}

**Proof of Proposition C.1** Pick any even \( n \in \mathbb{N} \). Let \( m := \frac{2n}{3} \). Let \( \beta > 0 \) be a small constant that we will fix later. We will divide the items into the following three types:
• Type A: For each \( 1 \leq i \leq \frac{n}{2} \) and \( 1 \leq j \leq n \),
  \[ P_{ij} := 0 = 1 - P_{i2} \text{ and } W_{ij} := 1. \]

• Type B: For each \( \frac{n}{2} + 1 \leq i \leq n \) and \( 1 \leq j \leq n \),
  \[ P_{ij} := \frac{1}{2} + \beta = 1 - P_{i2} \text{ and } W_{ij} := 1. \]

• Type C: For each \( n + 1 \leq i \leq \frac{3n}{2} \) and \( 1 \leq j \leq n \),
  \[ P_{ij} := 1 = 1 - P_{i2} \text{ and } W_{ij} := 0. \]

Let \( \hat{G}_1 \) and \( \hat{G}_2 \) be the groups imputed using maximum likelihood rounding. By construction, \( \hat{G}_1 \) contains all items of Types A and B and no items of Type C, whereas \( \hat{G}_2 \) contains all items of Type C and no items of Types A and B.

Let \( R \) be an optimal solution of Program (2) with parameters \( G_1 = \hat{G}_1 \) and \( G_2 = \hat{G}_2 \). Since \( W_{ij} \leq 1 \) for all \( i \in [m], j \in [n] \),
  \[ \langle R, W \rangle \leq n. \]

Because \( R \) satisfies the equal representation constraints for two disjoint groups, for any even \( k \in [n] \), \( R \) places exactly \( \frac{k}{2} \) items of Type A and \( \frac{k}{2} \) items of Type B in the top \( k \) positions. From \( \hat{G}_1 \), \( R \) only places items of Type A: If \( R \) picks no items of Type C, then \( \langle R, W \rangle = n \), whereas, if \( R \) picks one or more items of Type C, then \( \langle R, W \rangle \leq n - 1 \), which is a contradiction since there is a ranking with utility \( n \) that satisfies equal representation constraints (e.g., a ranking which places items of Type A and B in alternate positions).

Since all items of Type A are (always) in \( \hat{G}_2 \), \( R \) places at least \( \frac{k}{2} \) items from \( \hat{G}_2 \) in the first \( k \) positions. We will show that with probability larger than \( \frac{1}{2} \), at least \( \frac{k}{2} \) of the \( k \) items of Type B are in \( \hat{G}_2 \). Thus, with probability larger than \( \frac{1}{2} \), \( R \) places more than \( \frac{k}{2} \cdot \frac{1}{10} \) items from \( \hat{G}_2 \) in the top-\( k \) positions, and hence, \( R \) does not satisfy the \((\varepsilon, \delta)\)-equal representation constraint for any \( \delta < \frac{1}{2} \) and \( \varepsilon \in (0, \frac{1}{10}) \).

It remains to prove our claim. Select any \( k \in \{2, 4, \ldots, n\} \). Let \( i_1, i_2, \ldots, i_{k/2} \in [m] \) be the \( n \) items of Type B that \( R \) places in the first \( k \) positions. Let \( Z_{i_j} \in \{0, 1\} \) be the indicator random variable that \( i_j \in \hat{G}_2 \). Thus, \( Z_{i_1}, \ldots, Z_{i_{k/2}} \) are independent random variables, such that, for \( j \in [k] \), \( \Pr[Z_{i_j}] = 1 - P_{i_j} = \frac{1}{2} - \beta \). It follows that \( \mathbb{E}[\sum_{j=1}^{k/2} Z_{i_j}] = k \left( \frac{1}{2} - \beta \right) \) and \( \text{Var}[\sum_{j=1}^{k/2} Z_{i_j}] = \frac{k}{2} \left( \frac{1}{2} - \beta^2 \right) \).

Thus, using the Chebyshev's inequality on \( \sum_{j=1}^{k/2} Z_{i_j} \),
  \[ \Pr \left[ \left| \sum_{j=1}^{k/2} Z_{i_j} - \frac{k}{4} \left( 1 - 2\beta \right) \right| > \frac{k}{8} \left( 1 - 4\beta^2 \right) \cdot \sqrt{2 + \beta} \right] \leq \frac{1}{2 + \beta}. \]

Thus,
  \[ \Pr \left[ \sum_{j=1}^{k/2} Z_{i_j} \leq \frac{k}{4} \left( 1 - 2\beta \right) - \frac{k}{8} \left( 1 - 4\beta^2 \right) \cdot \sqrt{2 + \beta} \right] \leq \frac{1}{2 + \beta}. \]

Since \( \frac{k}{4} \left( 1 - 2\beta \right) - \frac{k}{8} \left( 1 - 4\beta^2 \right) \cdot \sqrt{2 + \beta} = k \left( \frac{1}{2} - \frac{\sqrt{2}}{8} \right) + k \cdot O(\beta) \), for a sufficiently small \( \beta > 0 \),
  \[ \frac{k}{4} \left( 1 - 2\beta \right) - \frac{k}{8} \left( 1 - 4\beta^2 \right) \cdot \sqrt{2 + \beta} > \frac{k}{20}. \]

Hence,
  \[ \Pr \left[ \sum_{j=1}^{k/2} Z_{i_j} < \frac{k}{20} \right] \leq \frac{1}{2 + \beta} < \frac{1}{2}. \] (15)
C.2 Proof of Proposition C.2

Proof of Proposition C.2. Let $\phi > 0$ be a small constant that we will fix later. We will divide the items into the following two types:

- **Type A:** For each item $i$ of Type A
  \[ P_{i1} := \phi, \quad P_{i2} := 1 - \phi \quad \text{and} \quad W_{ij} := 1 \quad \text{for all} \quad j \in [n]. \]

- **Type B:** For each item $i$ of Type B
  \[ P_{i1} := 1, \quad P_{i2} := 0 \quad \text{and} \quad W_{ij} := 0 \quad \text{for all} \quad j \in [n]. \]

- **Type B:** For each item $i$ of Type C
  \[ P_{i1} := 0, \quad P_{i2} := 1 \quad \text{and} \quad W_{ij} := 0 \quad \text{for all} \quad j \in [n]. \]

Let there be $m_A := O \left( \frac{\log \left( \frac{n}{\beta} \right) \cdot \frac{n}{\log \left( \frac{1}{1-\phi} \right)}}{\phi} \right)$ items of Type A, $m_B := n$ items of Type B, and $m_C := n$ items of Type C.

Note that a ranking which ranks items of Type B and Type C alternately, satisfies the equal representation constraints with probability 1. So in this instance, there exists a ranking which satisfies $(\delta, \varepsilon)$-equal representation with probability at least $1 - \beta$.

Let $G_1$ and $G_2$ be the groups imputed by independent rounding. Let $\mathcal{E}$ be the event that $G_1$ contains at least $n$ items of Type A and $\mathcal{F}$ be the event that $G_2$ contains at least $n$ items of Type A. Both $\mathcal{E}$ and $\mathcal{F}$ occur with probability at most $O(\beta)$. To see this, divide the items of Type A into $n$ groups of equal size. From each group, at least one item is selected in $G_1$ and $G_2$ with probabilities at least $1 - (1 - \phi) \frac{m_A}{n}$ and $1 - (\phi) \frac{m_A}{n}$ respectively. Taking a union bound over all groups and substituting $m_A$, we get

\[ \Pr[\mathcal{E}] \geq 1 - \beta \quad \text{and} \quad \Pr[\mathcal{F}] \geq 1 - \beta. \]

Since only items of Type A have a nonzero contribution to the utility of a ranking and because there are at least $n$ items of Type A in each imputed group, it follows that $R$ only selects items of Type A. Now, the claim follows because, for small $\phi$, most items of Type A belong to $G_1$.

Suppose $\mathcal{E}$ and $\mathcal{F}$ happen and, hence, $R$ only selects items of Type A. Let $Z_j$ be the indicator random variable that the item in the $j$-th position of $R$ is in $G_1$. We have that $\Pr[Z_j = \phi]$. Therefore, $\text{Var} \left[ \sum_{j=1}^{n} Z_j \right] = n \phi (1 - \phi)$. Thus, using the Chebyshev’s inequality we have

\[ \Pr \left[ \left| \sum_{j=1}^{n} Z_j - n \phi \right| \geq \frac{n\varepsilon_n}{4} \right] \leq \frac{4n\phi(1 - \phi)}{n^2 \varepsilon_n^2}. \]

Hence, for $\phi = \Theta(\varepsilon_n^2 / \beta)$, we have that

\[ \Pr \left[ \sum_{j=1}^{n} Z_j \leq \frac{n\varepsilon_n}{2} \right] \geq 1 - \beta. \]

The result follows since whenever $\sum_{j=1}^{n} Z_j \leq \frac{n\varepsilon_n}{2}$, $R$ violates the equal representation constraint at the $n$-th position by a multiplicative factor larger than $1 + \varepsilon_n$. \qed
D Proofs of Theorems 4.2 and 4.3

D.1 Proof of Theorem 4.2

We consider the family of matrices $U \in \mathbb{R}^{n \times p}$ that satisfy the following condition: For each position $k \in [n]$, there exists an attribute $\ell$ such that

$$U_{k\ell} \leq \frac{k}{4}.$$  

Notably, equal representation constraints satisfy this condition for any $p \geq 4$. We will use Fact D.1 to prove Theorem 4.2.

Fact D.1 (Theorem 2 in [53]). For all $p \in (0, \frac{1}{4}]$, $0 \leq \varepsilon \leq \frac{1}{p}(1 - p)$, and $s \in \mathbb{N}$ independent 0/1 random variables $Z_1, Z_2, \ldots, Z_s \in \{0, 1\}$, such that for all $i \in [s]$, $\Pr[Z_i = 1] = p$,

$$\Pr\left[\sum_{i \in [s]} Z_i \geq (1 + \varepsilon)p s\right] \geq \frac{1}{4} \exp\left(-2\varepsilon^2 p s\right).$$

Proof of Theorem 4.2 Fix the $k$ to the value specified in the theorem. Let $\ell \in [n]$, be any attribute such that $U_{k\ell} \leq \frac{k}{4}$. Such a $\ell$ exists because of the family of constraints we chose. Without loss of generality suppose $\ell \neq 1$. Fix any $n, m \geq k$. For each item $i \in [m]$, set

$$P_{i\ell} := \frac{U_{k\ell}}{k} \quad \text{and} \quad P_{i1} := 1 - \frac{U_{k1}}{k} \quad \text{(16)}$$

Further, for all $k \in [p]$, $k \neq p$ and $k \neq 1$, let $P_{kk} := 0$.

Suppose, toward a contradiction, that there is a ranking $R \in \mathcal{R}$ that satisfies the $(\varepsilon, \delta)$-constraint. $R$ must satisfy the following equation:

$$\Pr[Z_\#(R, k, \ell) \leq U_{k\ell} \cdot (1 + \varepsilon_k)] \geq 1 - \delta. \quad \text{(17)}$$

For each position $j \in [n]$, let $Z_j \in \{0, 1\}$ be the indicator random variable that the item placed in the $j$-th place in the ranking $R$ is in the protected group $G_\ell$. From Equation (16) and Definition 3.2 it follows that:

$$\forall j \in [n], \quad P[Z_j] = \frac{U_{k\ell}}{k}, \quad \text{(18)}$$

$$\forall u, v \in [n], \quad \text{s.t., } u \neq v, \quad Z_u \text{ and } Z_v \text{ are independent.} \quad \text{(19)}$$

Using linearity of expectation and Equation (18), we get that:

$$\Pr[Z_\#(R, k, \ell) \leq (1 + \varepsilon_k) \cdot U_{k\ell}] = \Pr\left[\sum_{j \in [k]} Z_j \geq (1 + \varepsilon_k) \cdot \mathbb{E}\left[\sum_{j=1}^{k} Z_j\right]\right]. \quad \text{(20)}$$

Since $0 \leq \varepsilon_k \leq 1$ and $\frac{1}{k} \mathbb{E}\left[\sum_{j=1}^{k} Z_j\right] \leq \frac{1}{4}$, we can use Fact D.1 with $\varepsilon := \varepsilon_k$, $p := \frac{1}{k} \mathbb{E}\left[\sum_{j=1}^{k} Z_j\right] \leq \frac{1}{4}$, $s := k$, and for all $j \in [n]$, $Z_j = Z_j$. Using this, we get that

$$\Pr\left[\sum_{j \in [k]} Z_j \geq (1 + \varepsilon_k) \cdot \mathbb{E}\left[\sum_{j=1}^{k} Z_j\right]\right] \leq 1 - \frac{1}{4} \exp\left(-2\varepsilon_k^2 \cdot \mathbb{E}\left[\sum_{j=1}^{k} Z_j\right]\right) \leq 1 - \frac{1}{4} \exp\left(-2\varepsilon_k^2 U_{k\ell}\right). \quad \text{(Using Equation (18)) (21)}$$

Chaining Equations (17), (20), and (21), we get that

$$1 - \frac{1}{4} \exp\left(-2\varepsilon_k^2 U_{k\ell}\right) \geq 1 - \delta.$$
Hence,
\[ \varepsilon_k \geq \frac{1}{2U_{k\ell}} \log \frac{1}{4\delta}. \]
This is a contradiction since \( \varepsilon_k \) is specified to be less than \( \sqrt{\frac{1}{2U_{k\ell}} \log \frac{1}{4\delta}} \). Thus, no ranking \( R \) satisfies the \((\varepsilon, \delta)\)-constraint for any \( U \) in the chosen family chosen.

\[ \square \]

D.2 Proof of Theorem 4.3

In this section, we prove Theorem 4.3. Our algorithm uses the dependent-rounding algorithm of [19] as a subroutine.

Remark. Desirable properties and potential approaches for rounding. At a high level, the goal of this dependent-rounding algorithm is the following: Given a feasible solution \( R_c \) of the standard linear programming relaxation of Program (7) output a ranking \( R \) such that for any matrix \( A \) with nonnegative entries, \( \langle R, A \rangle \) is approximately equal to \( \langle R_c, A \rangle \). This property guarantees that, with high probability, \( R \) approximately satisfies the fairness constraints and has a similar utility as \( R_c \).

Another approach is (1) to express \( R_c \) as a convex combination of rankings \( \sum_i \alpha_i R_i \) (\( \alpha_i \geq 0 \)) (e.g., using the Birkhoff von Neumann decomposition) and (2) set \( R := R_i \) with probability \( \propto \alpha_i \). Since each \( R_i \) is a ranking this guarantees that \( R \) is a ranking, but it may violate fairness constraints significantly. For example, consider the fractional assignment in which the \( k \)-th best female (respectively male) appears in the \( k \)-th position with weight 0.5 for all positions \( k \). This can be decomposed into two rankings: 1) females are ranked in decreasing order of utility, and 2) males are ranked in decreasing order of utility. The fractional solution satisfies equal representation, but both rankings violate equal representation significantly.

The dependent-rounding algorithm of [19], which we use, also expresses \( R_c \) as a convex combination of rankings \( \sum_i \alpha_i R_i \) (\( \alpha_i \geq 0 \)). But it does not output \( R_i \) for any \( i \). Instead, it initially, sets \( R := R_1 \). Then it iteratively “merges” \( R \) with \( R_2 \), then \( R_3 \), and so on.

[19]’s algorithm satisfies the following guarantees.

Theorem D.2 (Theorem 1.1 from [19]). Let \( P \subseteq [0, 1]^N \) be either a matroid intersection polytope or a (non-bipartite graph) matching polytope. For any fixed \( 0 < \alpha \leq \frac{1}{4} \), there is an efficient randomized rounding procedure, such that given a (fractional) point \( R_F \in P \), it outputs a random feasible solution \( R \) corresponding to an (integer) vertex of \( P \) such that \( \mathbb{E}[1_R] = (1 - \alpha) \cdot R_F \). In addition, for any linear function \( w(R) := \sum_{i \in R} w_i \), where \( w_i \in [0, 1] \) it holds that

1. for any \( \delta \in [0, 1] \) and \( \mu \leq \mathbb{E}[1_R] \), \( \Pr[w(R) \leq (1 - \delta)\mu] \leq \exp \left( -\frac{1}{20} \cdot \mu \alpha \delta^2 \right) \).
2. for any \( \delta \in [0, 1] \) and \( \mu \geq \mathbb{E}[1_R] \), \( \Pr[w(R) \geq (1 - \delta)\mu] \leq \exp \left( -\frac{1}{20} \cdot \mu \alpha \delta^2 \right) \).
3. for any \( \Delta \geq 1 \) and \( \mu \geq \mathbb{E}[1_R] \), \( \Pr[w(R) \geq \mu(1 + \Delta)] \leq \exp \left( -\frac{1}{20} \cdot \mu \alpha (2\Delta - 1) \right) \).

The algorithm runs in time polynomial in the size of the ground set, \( N \), and \( \frac{1}{\alpha} \), and makes at most \( \text{poly}(N, d) \) calls to the independence oracles for the underlying matroids.

We claim that the following algorithm satisfies the claim in Theorem 4.3.

For each item \( i \in [m] \) and protected attribute \( \ell \in [p] \), let \( Z_{i\ell} \in \{0, 1\} \) be the indicator random variable that the \( i \)-th item is in the \( \ell \)-th protected group, i.e., if \( i \in G_{\ell} \), then \( Z_{i\ell} = 1 \), and other \( Z_i = 0 \).

Using Definition 3.2, it follows that:

\[
\forall i \in [m], \ell \in [p], \quad \Pr[Z_{i\ell}] = P_{i\ell},
\]

\[
\forall i, j \in [m], \ell \in [p], \quad \text{s.t., } i \neq j, \quad Z_{i\ell} \text{ and } Z_{j\ell} \text{ are independent.}
\]
Algorithm 1 Algorithm from Theorem 4.3

Input: Matrices \( P \in [0,1]^{m \times p}, W \in \mathbb{R}_{\geq 0}^{m \times n}, U \in \mathbb{R}^{n \times p} \)

Parameters: Constant \( d > 2 \) and \( c > 1 \), a failure probability \( \delta \in (0,1] \), and for each \( k \in [n] \), a relaxation parameter

\[
\gamma_k := 12 \cdot \log \left( \frac{2np}{\delta} \right) \cdot \max_{\ell \in [p]} \sqrt{\frac{1}{U_{k\ell}}},
\]

1. Initialize \( R_F \leftarrow \) Solve the linear-programming relaxation of Program (7) with the specified inputs
2. Round \( R \leftarrow \) Run [19]'s rounding algorithm with input \( \alpha := \frac{4}{\gamma} \) and \( F := \text{conv}(R) \)
3. Return \( R \)

To simplify the notation, given a ranking \( R \in \mathcal{R} \), a protected attribute \( \ell \in [p] \), and a position \( k \in [n] \), let \( Z_\#(R, \ell, k) \in \mathbb{Z} \) be the random variable equal to the number of items from \( G_\ell \) in the top \( k \) positions of \( R \) and let \( P_\#(R, \ell, k) \in \mathbb{R} \) be the expectation of \( Z_\#(R, \ell, k) \), i.e.,

\[
Z_\#(R, \ell, k) := \sum_{i \in [m]} \sum_{j \in [k]} Z_{ij} R_{ij} \quad \text{and} \quad P_\#(R, \ell, k) := \mathbb{E}[Z_\#(R, \ell, k)].
\]

Using Equation (22) and linearity of expectation it follows that

\[
P_\#(R, \ell, k) = \sum_{i \in [m]} \sum_{j \in [k]} P_{ij} R_{ij}.
\]

**Proof.**

**Running time.** The Step 1 of Algorithm 1 runs in polynomial time when implemented with any polynomial-time linear programming solver. Observe that \( \mathcal{R} \) corresponds to the bipartite matching polytope, whose bi-partitions have size \( n \) and \( m \) respectively. Since the bipartite matching polytope is a matroid intersection polytope, we can use Theorem D.2. The independence oracle for this polytope can be implemented in \( \text{poly}(m) \) time, e.g., using the Birkhoff–von Neumann theorem. Finally, since \( \alpha = \frac{4}{\gamma} \) and \( N = \mathcal{O}(m^2) \), it follows that Step 2 of Algorithm 1 runs in polynomial time in \( d \) and the bit complexity of the input (which is at least \( m \)).

Let

\[
\phi := \frac{2\sqrt{c} - 1}{2\sqrt{c}}.
\]

Let \( R_F \) and \( R \) be the rankings from Steps 1 and 2 of Algorithm 1. From Theorem D.2 we have that \( \mathbb{E}[1_R] = (1 - \alpha) \cdot R_F \). Hence, for any weights \( V \in \mathbb{R}^{n \times m} \), it holds that

\[
\mathbb{E}[\langle R, V \rangle] = (1 - \alpha) \cdot \langle R_F, V \rangle. \tag{24}
\]

Fix any position \( k \in [n] \) and group \( \ell \in [p] \). Since \( \ell, k, \) and \( R \) are fixed, we use \( Z_\#(R) \) and \( Z_\#(R') \) and \( P_\# \) to denote \( Z_\#(R, \ell, k) \) and \( P_\#(R, \ell, k) \) respectively.

**Utility guarantee.** Let \( R^* \) be the solution of Program (7) for \( c = d \). Let \( V := \langle W, R^* \rangle \). Let \( 0 \leq \Delta \leq V \) be a parameter. Since \( R_F \) is a solution of the LP-relaxation of Program (7) and \( R^* \) is a solution of Program (7), \( R_F \)'s utility is at least as large as the utility of \( R^* \). From this it follows that

\[
\mathbb{P} \left[ \langle W, R \rangle \leq \langle W, R^* \rangle \cdot (1 - \alpha) - \Delta \right] \leq \mathbb{P} \left[ \langle W, R \rangle \leq \langle W, R_F \rangle \cdot (1 - \alpha) - \Delta \right]. \tag{25}
\]

Since \( W \in [0,1]^{m \times n} \), we can use Theorem D.2 with \( a = W \). Using this we get can upper bound the RHS of the above equation.

\[
\mathbb{P} \left[ \langle W, R \rangle \leq \langle W, R_F \rangle \cdot (1 - \alpha) - \Delta \right] = \mathbb{P} \left[ \langle W, R \rangle \leq \mathbb{E}[\langle W, R \rangle] - \Delta \right] \quad \text{(Using Equation (24))}
\leq \exp \left( -\frac{\alpha \cdot \Delta^2}{20 \cdot \langle W, R_F \rangle \cdot (1 - \alpha)} \right).
\]
Let $\Delta := \sqrt{\frac{20}{\pi} \cdot (W, R_F) \cdot (1 - \alpha) \cdot \log \left( \frac{2np}{\delta} \right)}$. Substituting the value of $\Delta$ in the above equation, we have:

$$\Pr [(W, R) \leq E[(W, R)] - \Delta] \leq \frac{\delta}{2np}.$$  \hspace{1cm} (26)

Chaining the inequalities in Equations (25) and (26)

$$\Pr [(W, R) \leq (W, R^*) \cdot (1 - \alpha) - \Delta] \leq \frac{\delta}{2n}.$$  

Since each entry of $W$ is at most 1 and $\sum_{i,j} (R_F)_{ij} = n$, it follows that $\langle W, R_F \rangle \leq n$. Using this and that $\alpha = \frac{1}{d}$,

$$\Delta = O \left( \sqrt{dn \cdot \log \frac{2np}{\delta}} \right).$$

Thus, the utility guarantee follows.

**Fairness guarantee.** Since $R_F$ is feasible for the LP-relaxation of Program (7), it holds that

$$P_\#(R_F) \leq U_{k\ell}(1 + \phi \gamma_k).$$  \hspace{1cm} (27)

Let $\varepsilon > 0$ be some constant such that

$$\varepsilon \geq \phi \gamma_k.$$  \hspace{1cm} (28)

We divide the analysis into two cases depending on the value of $\varepsilon$.

**Case A** ($P_\#(R) \geq \frac{1}{2} U_{k\ell}(1 + \varepsilon)$): Since $P_\#(R) \geq \frac{1}{2} \cdot U_{k\ell}(1 + \varepsilon)$, we have that

$$\frac{U(1 + \varepsilon) - P_\#(R)}{P_\#(R)} \leq 1.$$  \hspace{1cm} (29)

We have that

$$\Pr [Z_\#(R) > U_{k\ell}(1 + \varepsilon)] = \Pr [Z_\#(R) > P_\#(R) \cdot \left( 1 + \frac{U_{k\ell}(1 + \varepsilon) - P_\#(R)}{P_\#(R)} \right)].$$

From Equation (24) it follows that $P_\#(R) = P_\#(R_F)(1 - \alpha)$. Then from Equations (27) and (28) we have that $P_\#(R) \leq U_{k\ell}(1 + \varepsilon)$. Hence, $\frac{U_{k\ell}(1 + \varepsilon) - P_\#(R)}{P_\#(R)} \geq 0$. Further, from Equation (29) we have that $\frac{U_{k\ell}(1 + \varepsilon) - P_\#(R)}{P_\#(R)} \leq 0$. Hence, we can use the second statement of Theorem D.2. Using this we get

$$\leq \exp \left( -\frac{\alpha}{20} \cdot P_\#(R) \cdot \left( \frac{U_{k\ell}(1 + \varepsilon) - P_\#(R)}{P_\#(R)} \right)^2 \right)$$

$$\leq \exp \left( -\frac{\alpha}{20} \cdot P_\#(R_F) \cdot \left( \frac{U_{k\ell}(1 + \varepsilon) - P_\#(R_F)}{P_\#(R_F)} \right)^2 \right)$$

(Fact E.2 and that $P_\#(R) \leq P_\#(R_F)$)

$$\leq \exp \left( -\frac{\alpha}{20} \cdot U_{k\ell} \cdot \frac{(\varepsilon - \phi \gamma_k)^2}{1 + \phi \gamma_k} \right).$$

(Fact E.2 and Equation (27))  \hspace{1cm} (30)

**Case B** ($P_\#(R) < \frac{1}{2} U_{k\ell}(1 + \varepsilon)$): Since $P_\#(R) < \frac{1}{2} \cdot U_{k\ell}(1 + \varepsilon)$, we have that

$$\frac{U_{k\ell}(1 + \varepsilon) - P_\#(R)}{P_\#(R)} \geq 1.$$  \hspace{1cm} (31)
We have that

\[
\operatorname{Pr}[Z(R) > U_k \ell (1 + \varepsilon)] = \operatorname{Pr}\left[Z(R) > P(R) \cdot \left(1 + \frac{U_k \ell (1 + \varepsilon) - P(R)}{P(R)}\right)\right] \\
\leq \exp\left(-\frac{\alpha}{20} \cdot P(R) \cdot \left(2 \cdot \frac{U_k \ell (1 + \varepsilon) - P(R)}{P(R)} - 1\right)\right) \\
(\text{Using third statement in Theorem D.2 and that Equation (31)}) \\
= \exp\left(-\frac{\alpha}{20} \cdot (2U_k \ell (1 + \varepsilon) - 3P(R))\right) \\
\leq \exp\left(-\frac{\alpha}{40} \cdot U_k \ell (1 + \varepsilon)\right). \\
(\text{Using that } P(R) < \frac{1}{2} \cdot U_k \ell (1 + \varepsilon)) \\
\tag{32}
\]

Combining Equations (30) and (32) we get that

\[
\operatorname{Pr}[Z(R) > U \ell (1 + \varepsilon)] \leq \max\left\{\exp\left(-\frac{\alpha}{20} \cdot U_k \ell (1 + \varepsilon)\right), \exp\left(-\frac{\alpha}{40} \cdot U_k \ell (1 + \varepsilon)\right)\right\}. \\
\tag{33}
\]

Let

\[
\varepsilon := \frac{40}{\alpha} \cdot \gamma_k. \\
\tag{34}
\]

We claim that for this value of \(\varepsilon\), it holds that

\[
\operatorname{Pr}[Z(R) > U_k \ell (1 + \varepsilon)] \leq \frac{\delta}{2n}. \\
\tag{35}
\]

Now by taking a union bound over bound over all \(\ell \in [n]\) and using that \(\alpha := \frac{1}{2}\), it follows that \(R\) satisfies the fairness guarantee with probability at least \(\frac{\delta}{2n}\).

We can upper bound the second term in Equation (33), as follows

\[
\exp\left(-\frac{\alpha}{40} \cdot U_k \ell (1 + \varepsilon)\right) \leq \exp\left(-\frac{\alpha}{40} \cdot U_k \ell \cdot \varepsilon\right) \\
\leq \exp\left(-U_k \ell \cdot \gamma_k\right) \\
\leq \frac{\delta}{np}. \\
(\text{Using that } \gamma_k \geq \frac{1}{U_k \ell} \cdot \log \frac{2np}{\delta}; \text{ which follows from Equation (6), } U_k \ell \geq 1, \text{ and } \log \frac{2np}{\delta} \geq 1)
\]

To upper bound the first term in Equation (33), we use Fact D.3

**Fact D.3.** For all \(x, y \geq 0\), if \(x \geq y + \sqrt{y}\), then \(\frac{x^2}{1+x} \geq y\).

**Proof.** Since \(1 + x > 0\), \(\frac{x^2}{1+x} \geq y\) holds if and only if \(x^2 - xy - y \geq 0\). The roots of the quadratic \(f(x) := x^2 - xy - y\) are

\[
y \frac{1}{2} - \sqrt{\frac{y^2}{4} + y} \quad \text{and} \quad y \frac{1}{2} + \sqrt{\frac{y^2}{4} + y}.
\]

If \(x\) is larger than both roots, then \(f(x) \geq 0\) and, hence, \(\frac{x^2}{1+x} \geq y\). It follows that \(x \geq y \frac{1}{2} + \sqrt{\frac{y^2}{4} + y}\) suffices. Then using that for all \(a, b \geq 0\), \(\sqrt{a} + \sqrt{b} \geq \sqrt{a+b}\), we get that

\[
y + \sqrt{y} \geq y \frac{1}{2} + \sqrt{\frac{y^2}{4} + y}.
\]

Thus, it suffices \(x \geq y + \sqrt{y}\) implies that \(\frac{x^2}{1+x} \geq y\). \(\square\)
We have
\[
\frac{(\varepsilon - \phi \gamma_k)^2}{1 + \phi \gamma_k} \geq \left(\frac{39}{\alpha}\right)^2 \cdot \frac{\gamma_k}{1 + \phi \gamma_k} \geq \frac{\gamma_k^2}{1 + \gamma_k}.
\]
(Using that \(0 \leq \phi \leq 1\), \(\alpha \leq \frac{1}{2}\), and Equation (34))

To proof Equation (35), it suffices to prove that
\[
\frac{\gamma_k^2}{1 + \gamma_k} \geq \frac{1}{U_{k\ell}} \cdot \log \left(\frac{n + 2}{\delta}\right).
\]
(36)

Further, Fact D.3 implies that to prove Equation (36) it suffices to prove that
\[
\gamma_k \geq y + \sqrt{y},
\]
where \(y := \frac{1}{U_{k\ell}} \cdot \log \frac{n + 2}{\delta}\). To prove this, observe that
\[
\log \frac{np}{\delta} \cdot \frac{1}{U_{k\ell}} \leq \log \frac{np}{\delta} \cdot \sqrt{\frac{1}{U_{k\ell}}} \quad \text{(Using that } U_{k\ell} \geq 1\text{)}
\]
\[
\sqrt{\log \frac{np}{\delta} \cdot \frac{1}{U_{k\ell}}} \leq \log \frac{np}{\delta} \cdot \sqrt{\frac{1}{U_{k\ell}}} \quad \text{(Using that } \log \frac{np}{\delta} \geq \frac{1}{2} \text{ as } n \geq 1 \text{ and } \delta \leq \frac{1}{2}\text{)}
\]

Hence, Equation (36) follows from Equation (6).

\[\square\]

E Proofs of additional theoretical results

E.1 Proof of Proposition 3.3

**Proof of Proposition 3.3** Suppose \(R\) is deterministic. Suppose it places items \(i, j \in [m]\) on the first and second position respectively. With probability \(p_i \cdot p_j = \frac{1}{4}\), both \(i\) and \(j\) belong to \(G_1\), and with probability \(p_i \cdot p_j = \frac{1}{4}\) both \(i\) and \(j\) belong to \(G_2\). Thus, at least one of these events occurs with probability \(\frac{1}{2}\). If either of these events hold, then \(R\) violates the equal representation constraint on the top-2 positions by a multiplicative factor of 2. The last two statements imply that \(R\) violates \((\rho, \delta)\)-equal representation for any \(\rho < 1\) and \(\delta < \frac{1}{2}\).

If \(R\) is a random variable, then any draw \(R'\) of \(R\) is a deterministic ranking, and hence, by the above argument \(R'\) violates the equal representation constraint on the top-2 positions by a multiplicative factor of 2. The last two statements imply that \(R\) violates \((\rho, \delta)\)-equal representation for any \(\rho < 1\) and \(\delta < \frac{1}{2}\). \(\square\)

E.2 Proof of Lemma 6.3

In this section, we prove certain concentration inequalities which are used in the proof of Theorem 4.1.

We divide the proof of Lemma 6.3 into two parts: Lemmas E.1 and E.6.

For each item \(i \in [m]\) and protected attribute \(\ell \in [p]\), let \(Z_{i\ell} \in \{0, 1\}\) be the indicator random variable that the \(i\)-th item is in the \(\ell\)-th protected group, i.e., if \(i \in G_\ell\), then \(Z_{i\ell} = 1\), and other \(Z_{i\ell} = 0\). Using Definition 3.2 it follows that:

\[
\forall i \in [m], \ell \in [p], \quad \Pr[Z_{i\ell}] = P_{i\ell},
\]
\[
\forall i, j \in [m], \ell \in [p], \quad \text{s.t., } i \neq j, \quad Z_{i\ell} \text{ and } Z_{j\ell} \text{ are independent.}
\]
To simplify the notation, given a ranking $R \in \mathcal{R}$, a protected attribute $\ell \in [p]$, and a position $k \in [n]$, let $Z\#(R, \ell, k) \in \mathbb{Z}$ be the random variable equal to the number of items from $G_\ell$ in the top $k$ positions of $R$ and let $P\#(R, \ell, k) \in \mathbb{R}$ be the expectation of $Z\#(R, \ell, k)$, i.e.,

$$Z\#(R, \ell, k) := \sum_{i \in [m]} \sum_{j \in [k]} Z_{ij} R_{ij} \quad \text{and} \quad P\#(R, \ell, k) := \mathbb{E}[Z\#(R, \ell, k)].$$

Using Equation (37) and linearity of expectation it follows that

$$P\#(R, \ell, k) = \sum_{i \in [m]} \sum_{j \in [k]} P_{ij} R_{ij}.$$ 

**Lemma E.1.** For any position $k \in [n]$, attribute $\ell \in [p]$, parameters $\varepsilon \geq 0$ and $L \in \mathbb{R}$, and ranking $R \in \mathcal{R}$, where $R$ is possibly a random variable and is independent of $\{Z_{i\ell}\}_{i,\ell}$ if $P\#(R, \ell, k) \geq L$ then with probability at least $1 - \exp \left( -\frac{L\varepsilon^2}{2(1-\varepsilon)} \right)$, it holds that $Z\#(R, \ell, k) > L(1 - \varepsilon)$.

**Proof.** Since $\ell$, $k$, and $R$ are fixed, we use $Z\#$ and $P\#$ to denote $Z\#(R, \ell, k)$ and $P\#(R, \ell, k)$ respectively.

Since $R$ and $\{Z_{i\ell}\}_{i,\ell}$ are independent, we can bound the required probability as follows

$$\Pr[Z\# \leq L(1 - \varepsilon)] = \Pr[Z\# \leq P\# \cdot \left(1 - \frac{P\# - L(1 - \varepsilon)}{P\#}\right)]$$

$$\leq \exp \left(-\frac{P\#}{2} \left(\frac{P\# - L(1 - \varepsilon)}{P\#}\right)^2\right) \quad \text{(Chernoff bound, see (52))}$$

$$= \exp \left(-\frac{1}{2} \cdot \frac{(P\# - L(1 - \varepsilon))^2}{P\#}\right). \quad (39)$$

To bound the right-hand side of Equation (39), we will use the following fact.

**Fact E.2.** For all $L, \varepsilon > 0$, $\frac{(x - L(1 - \varepsilon))^2}{x}$ attains its minima at $L$ over the domain $[L, \infty)$.

Since $P\# \geq L$, from Fact E.2 it follows that the right-hand side of Equation (39) attains its maxima at $P\# = L$. Substituting $P\# = L$ in Equation (39), we get:

$$\Pr[Z\# \leq L(1 - \varepsilon)] \leq \exp \left(-\frac{1}{2} \cdot \frac{(L\varepsilon)^2}{L(1 - \varepsilon)}\right) = \exp \left(-\frac{L\varepsilon^2}{2(1 - \varepsilon)}\right).$$

**Lemma E.3.** For any position $k \in [n]$, attribute $\ell \in [p]$, parameters $\varepsilon \geq 0$ and $U \in \mathbb{R}$, and ranking $R \in \mathcal{R}$, where $R$ is possibly a random variable and is independent of $\{Z_{i\ell}\}_{i,\ell}$ if $R$ satisfies that $P\#(R, \ell, k) \leq U$ then with probability at least $1 - \exp \left(-\frac{U\varepsilon^2}{2(1+\varepsilon)}\right)$, it holds that $Z\#(R, \ell, k) < (1 + \varepsilon) \cdot U$.

**Proof.** Since $\ell$, $k$, and $R$ are fixed, we use $Z\#$ and $P\#$ to denote $Z\#(R, \ell, k)$ and $P\#(R, \ell, k)$ respectively. Since $R$ and $\{Z_{i\ell}\}_{i,\ell}$ are independent, we can bound the required probability as follows

$$\Pr[Z\# \geq U(1 + \varepsilon)] = \Pr[Z\# \leq P\# \cdot \left(1 + \frac{U(1 + \varepsilon) - P\#}{P\#}\right)]$$

$$\leq \exp \left(P\# \cdot \left(\frac{U(1 + \varepsilon) - P\#}{P\#}\right)^2 \cdot \frac{1}{2 + \frac{U(1 + \varepsilon) - P\#}{P\#}}\right).$$
Where we used the fact that: For any $\delta > 0$ and independent 0/1 random variables $Y_1, Y_2, \ldots, Y_n$, 
$\Pr[\sum Y_i > (1 + \delta)\mu] < \exp\left(\frac{-\mu^2}{2\delta^2}\right)$, where $\mu := \mathbb{E}[\sum_i Y_i]$ (see[52]). Simplifying the right-hand side of the above equation, we get:

$$
\Pr[Z_\# \geq U(1 + \varepsilon)] = \exp\left(-\frac{(U(1 + \varepsilon) - P_\#)^2}{U(1 + \varepsilon) + P_\#}\right). \tag{40}
$$

To bound the right-hand side of Equation (40), we will use the following fact.

Fact E.4. For all $U, \varepsilon > 0$, $\frac{(U(1+\varepsilon) - x)^2}{U(1+\varepsilon) + x}$ attains its minima at $U$ over the domain $[0, U]$.

Since $P_\# \leq U$, from Fact E.4 it follows that the right-hand side of Equation (40) attains its maxima at $P_\# = U$. Substituting $P_\# = U$ in Equation (40), we get:

$$
\Pr[Z_\# \geq U(1 + \varepsilon)] \leq \exp\left(-\frac{U\varepsilon^2}{2 + \varepsilon}\right). \tag{41}
$$

\[\square\]

### E.3 Improved dependence of Theorem 4.1 on $\gamma$ on $\delta$

In this section, we show that given a constant $\psi > 0$, if $U$ satisfies that 
$$
\forall \ell \in [p], \forall k \in [n], \quad U_{\ell k} \geq \psi k,
$$

then we can improve the dependence of $\gamma$ (from Equation (6)) on $\log \frac{2np}{\delta}$ and $\alpha$. Concretely, Theorem 4.1 holds for the following $\gamma$:

$$
\forall k \in [n], \quad \gamma_k := \max_{\ell \in [p]} \sqrt{\frac{1}{2\psi} \cdot \log \left(\frac{2np}{\delta} \cdot \frac{1}{U_{\ell k}}\right)}.
$$

The proof of this relies on analogous of Lemmas E.1 and E.3, Lemma E.5 and E.6

**Lemma E.5.** For any position $k \in [n]$, attribute $\ell \in [p]$, parameter $\varepsilon \geq 0$, and lower bound constraint $L \in \mathbb{Z}_{\geq 0}^n$, and ranking $x \in \mathcal{R}$, if $x$ satisfies that $P_\#(R, \ell, k) \geq L$ then with probability at least $1 - \exp\left(-2L^2\varepsilon^2k^{-1}\right)$, it holds that $Z_\#(R, \ell, k) > L(1 - \varepsilon)$.

**Lemma E.6.** For any position $k \in [n]$, attribute $\ell \in [p]$, parameters $\varepsilon \geq 0$ and $U \in \mathbb{R}$, and ranking $R \in \mathcal{R}$, where $R$ is possibly a random variable and is independent of $\{Z_{it}\}_{i, t}$. If $R$ satisfies that $P_\#(R, \ell, k) \leq U$ then with probability at least $1 - \exp\left(-2U^2\varepsilon^2k^{-1}\right)$, it holds that $Z_\#(R, \ell, k) < U(1 + \varepsilon)$.

To prove the improved dependence of $\gamma$, it suffices to prove Propositions 6.1 and 6.2. For the new value of $\gamma$, their proofs change as follows:

**Proof of Proposition 6.1.** The parameters in Equation (9) remain the same. Hence, following the same argument, Equation (10) holds. Now, we can prove Equation (12) as follows:

$$
\Pr[Z_\#(R, \ell, k) \geq U_{\ell k}(1 + \phi\gamma_k)] = \Pr[Z_\#(R, \ell, k) \geq U'(1 + \zeta)]
$$

(Using that $U'(1 + \zeta) = U_{\ell k}(1 + \phi\gamma_k)$)

$$
\leq \exp\left(-\frac{2(U')^2\zeta^2}{k}\right) \quad (\text{Using Lemma E.6})
$$

$$
= \exp\left(-\frac{2(1 - \phi)^2U_{\ell k}^2\gamma_k^2}{k}\right) \quad (\text{Using Equation (9)})
$$

$$
\leq \exp\left(-\frac{\delta}{2np}\right) \quad (\text{Using Equation (12)})
$$

(43)
Proposition 6.1 follows by replacing Equation (12) by Equation (43) in the rest of its proof.

**Proof of Proposition 6.2.** The parameters in Equation (13) remain the same. Now, we can prove

\[
\Pr \left[ Z_\#(R', k, \ell) \leq U_{k\ell} \right] = \Pr \left[ Z_\#(R', k, \ell) \leq L' \cdot (1 - \zeta) \right]
\]

(Using that \( L'(1 - \zeta) = U_{k\ell}(1 + b\gamma_k) \))

\[
\leq \exp \left( -\frac{2(L')^2 \zeta^2}{k} \right) \quad \text{(Using Lemma E.5)}
\]

\[
= \exp \left( -\frac{2(\phi - b)^2\gamma_k^2 U_{k\ell}^2}{k} \right) \quad \text{(Using Equation (13))}
\]

\[
\leq \exp \left( -2\psi(\phi - b)^2\gamma_k^2 U_{k\ell} \right) \quad \text{(Using that } U_{k\ell} \geq \psi k)\]

\[
< \frac{\delta}{2np} \quad \text{(Using Equation (42) and Equation (13))}
\]

\[
< 1 - \delta. \quad \text{(Using that } \delta < \frac{1}{2} \text{ and } n \geq 1)\]

The rest of the proof is identical.

**Proof of Lemma E.5.** First, note that since \( x \) is not a function of the outcomes of the random variables \( Z_{it}, x \) is independent of the random variables \( \{Z_{it}\}_{i,t} \). Since \( \ell, k, \) and \( x \) are fixed, we use \( Z_\# \) and \( P_\# \) to denote \( Z_\#(R, \ell, k) \) and \( P_\#(R, \ell, k) \) respectively. Now, we can bound the required probability as follows

\[
\Pr \left[ Z_\# \leq L(1 - \varepsilon) \right] = \Pr \left[ Z_\# \leq P_\# \cdot \left( 1 - \frac{P_\# - L(1 - \varepsilon)}{P_\#} \right) \right]
\]

\[
\leq \exp \left( -\frac{2}{k} \cdot P_\#^2 \cdot \left( \frac{P_\# - L(1 - \varepsilon)}{P_\#} \right)^2 \right)
\]

(Where we used the fact that: For any \( \delta > 0 \) and bounded random variables \( Y_1, Y_2, \ldots, Y_n \in [0, 1], \Pr \left[ \sum_i Y_i < (1 - \delta)\mu \right] < \exp \left( -2\mu^2\delta^2n^{-1} \right) \), where \( \mu := \mathbb{E}[\sum_i Y_i] \))

\[
= \exp \left( -\frac{2}{k} \cdot (P_\# - L(1 - \varepsilon))^2 \right)
\]

\[
\leq \exp \left( -2L^2\varepsilon^2k^{-1} \right).
\]

\( \square \)

**Proof of Lemma E.6.** Since \( \ell, k, \) and \( R \) are fixed, we use \( Z_\# \) and \( P_\# \) to denote \( Z_\#(R, \ell, k) \) and \( P_\#(R, \ell, k) \) respectively. Since \( R \) and \( \{Z_{it}\}_{i,t} \) are independent, we can bound the required probability as follows

\[
\Pr \left[ Z_\# \geq U(1 + \varepsilon) \right] = \Pr \left[ Z_\# \leq P_\# \cdot \left( 1 + \frac{U(1 + \varepsilon) - P_\#}{P_\#} \right) \right]
\]

\[
\leq \exp \left( -\frac{2}{k} \cdot P_\#^2 \cdot \left( \frac{U(1 + \varepsilon) - P_\#}{P_\#} \right)^2 \right).
\]

Where we used the fact that: For any \( \delta > 0 \) and bounded random variables \( Y_1, Y_2, \ldots, Y_n \in [0, 1], \Pr \left[ \sum_i Y_i > (1 + \delta)\mu \right] < \exp \left( -2\mu^2\delta^2n^{-1} \right) \), where \( \mu := \mathbb{E}[\sum_i Y_i] \) (62). Simplifying the right-hand side of the above equation, we get

\[
\Pr \left[ Z_\# \geq U(1 + \varepsilon) \right] \leq \exp \left( -\frac{2}{k} \cdot (U(1 + \varepsilon) - P_\#)^2 \right)
\]

\[
\leq \exp \left( -\frac{2U^2\varepsilon^2}{k} \right). \quad \text{(Using that } P_\# \leq U)\]
E.4 NP-hardness result

Theorem E.7. Given constants $c > 1$ and vector $\gamma \in \mathbb{R}^n_{\geq 0}$, and matrices $P \in [0, 1]^{m \times p}$, $W \in \mathbb{R}^{m \times n}_{\geq 0}$, $U \in \mathbb{R}^{n \times p}$, it is NP-hard to decide if Program (7) is feasible.

Theorem E.7 follows from Theorem 5.2 of [48], which proves that checking the feasibility of the following program is NP-hard

$$\max_{x \in \{0, 1\}^m} \sum_{i=1}^m w^o_i x_i$$

s.t., $\forall \ell \in [p^o]$, $\sum_{i=1}^{m^o} q^o_{i\ell} x_i \leq U^o_{\ell}$,

$$\sum_{i=1}^{m^o} x_i = n^o.$$ (46)

Where we used a superscript "$^o$" on the variables of [48], to differentiate between ours and [48]'s variables. Theorem E.7 follows from Theorem 5.2 of [48] by observing that Program (46) is a special case of Program (7), when:

$n := n^o, m := m^o, p := p^o, \gamma := 1_n, P = q^o,$

$$\forall k \in [n], \gamma_k = 1,$$

$$U_{nk} = U^o_{\ell},$$

$$\forall k \in [n] \setminus \{1\}, U_{k\ell} = n,$$

$$\forall i \in [m], j \in [n], W_{ij} = w^o_i.$$ (47) (48)

Finally, we can choose any $c > 1$.

E.5 Proof of Proposition E.8

Given a non-empty subset $C \subseteq \mathcal{R}$ denoting a constraint, let $R_C$ be the ranking with the highest utility in $C$, i.e.,

$$R_C := \text{argmax}_{R \in C} \langle R, W \rangle.$$ (49)

In other words, $R_C$ is the utility maximizing ranking subject to satisfying the "constraint" $C$.

Proposition E.8. Let $C^*$ be the set of all rankings that satisfy $(\varepsilon, \delta)$-constraint. For any subset $C \subseteq \mathcal{R}$, such that $C \neq C^*$, at least one of the following holds:

- there exists a matrix $W \in \mathbb{R}^{m \times n}_{\geq 0}$ such that, $R_C$ does not satisfy $(\varepsilon, \delta)$-equal representation,

- there exists a matrix $W \in \mathbb{R}^{m \times n}_{\geq 0}$ such that, $\langle R_C, W \rangle \leq \langle R_{C^*}, W \rangle \cdot (1 - \frac{1}{n}).$

We will use the following lemma in the proof of Proposition E.8.

Lemma E.9. For all rankings $R \in \mathcal{R}$, there exists a matrix $W \in \mathbb{R}^{m \times n}_{\geq 0}$ such that for all other rankings $R' \in \mathcal{R}$, $R \neq R'$, it holds that $\langle R', W \rangle \leq \langle R, W \rangle \cdot (1 - \frac{1}{n}).$

Proof. Suppose $R$ ranks items $i_1, i_2, \ldots, i_n$, in that order, in the first $n$ positions. Pick $W \in [0, 1]^{n \times m}$ such that $W_{ij} = 1$ if $i = i_j$ and 0 otherwise. $R$ has utility $\langle W, R \rangle = \sum_{j=1}^n (W)_{i_jj} = n.$

We claim that $\langle W, R' \rangle \leq n - 1$. If this is true, then the lemma follows.

$^3$Theorem 5.2 of [48] states an NP-hardness result holds for a generalization of Program (46). However, in their proof they only consider the special case of Program (46). Thus, their proof also implies NP-hardness of Program (46).
Since $R \neq R'$, there exists a position $k \in [n]$ such that $(x_C)_{i_k k} = 0$. We can upper bound $\langle W, R' \rangle$ as follows:

$$\langle W, R' \rangle = \sum_{j=1}^{n} \sum_{i=1}^{m} I[i = i_j] (R')_{ij}$$

(By the choice of $W$)

$$= \sum_{j=1}^{n} (R')_{ij}$$

$$= \sum_{j=1}^{k-1} (R')_{ij} + 0 + \sum_{j=k+1}^{n} (R')_{ij}$$

(Using that $(R')_{ik} = 0$)

$$\leq n - 1.$$  

(Using that for all $i \in [m]$ and $j \in [n]$, $(W)_{ij} \leq 1$)

\[ \square \]

**Proof of Proposition E.8.** Since $C \neq C^*$, at least one of the sets $C \setminus C^*$ or $C^* \setminus C$ is nonempty. We divide the proof into two cases.

**Case A ($|C \setminus C^*| \neq 0$):** In this case, there exists a ranking $R \in C$ such that $R \not\in C^*$. Since $C^*$ is the set of all rankings that satisfy $(\varepsilon, \delta)$-constraint, it follows that $R$ does not satisfy $(\varepsilon, \delta)$-constraint. Further, from Lemma E.9, it follows that there exists a matrix $W$ such that $R := \argmax_{R' \in R} \langle R', W \rangle$. Since $C \subseteq R$, it follows that $R_C = R$. Therefore, for this $W$, $R_C$ does not satisfy $(\varepsilon, \delta)$-constraint.

**Case B ($|C^* \setminus C| \neq 0$):** In this case, there exists a ranking $R \in C^*$ such that $R \not\in C$. From Lemma E.9, it follows that there exists a matrix $W$ such that, for rankings $R'$ different from $R$ (i.e., $R \neq R'$),

$$\langle R', W \rangle \leq \langle R, W \rangle \cdot \left(1 - \frac{1}{n}\right).$$

Thus, for this $W$, it follows that

$$\langle R_C^*, W \rangle \cdot \left(1 - \frac{1}{n}\right) \geq \langle R, W \rangle \cdot \left(1 - \frac{1}{n}\right) \geq \langle R', W \rangle.$$

In particular, for $R' = R_C$, we get $\langle R_C^*, W \rangle \cdot \left(1 - \frac{1}{n}\right) \geq \langle R', W \rangle$.

\[ \square \]

**E.6 Proof of Lemma E.10**

Suppose there are two groups $G_1$ and $G_2$. Let $R_E$ be the optimal solution to Equation (5) and let $R^*$ be the ranking with the highest utility subject to satisfying $(\gamma, \delta)$-equal representation constraints for the following $\gamma$:

$$\forall k \in [n], \quad \gamma_k := \frac{1}{k} + 2 \sqrt{\frac{6}{k} \cdot \log \left(\frac{2n}{\delta}\right)}. \quad (49)$$

**Lemma E.10.** There exists a matrices $P \in [0, 1]^{m \times 2}$ and $W \in [0, 1]^{m \times 2}$ such that

- $R_E$ satisfies $(\gamma, \delta)$-equal representation and has utility 0.
- $R^*$ has utility 1.

**Proof.** Let $P$ be the matrix with $P_{1i} = P_{2i} = \frac{1}{2}$ for all $i \in \{1, 2, \ldots, m - 1\}$ and $P_{m1} = 1$ and $P_{m2} = 0$. Let $W$ be the matrix whose first $m - 1$ rows are 0, and the last row has is all 1s. Hence, only the last item, say $i_m$, has a nonzero contribution to the utility: If a ranking $R$ ranks $i_m$ in the first $n$ positions, then the utility of $R$ is 1, otherwise the utility of $R$ is 0.
Our first claim will follow because the choice of $P$ ensures that any ranking which ranks $i_m$ in the first $n$ positions cannot satisfy Equation (5). To see this, suppose $R$ ranks $i_m$ at the $k$-th position, then

$$
\mathbb{E}\left[\sum_{i \in G_1} \sum_{j=1}^{k} R_{ij}\right] = \sum_{i \in [m]} \sum_{j=1}^{k} P_{1i} R_{ij} \\
= 1 + \sum_{i \in [m] \setminus \{i_m\}} \sum_{j=1}^{k-1} P_{1i} R_{ij} \quad \text{(Using that $P_{1i_1} = 1$)} \\
= \frac{k + 1}{2} \quad \text{(Using that $P_{1i} = \frac{1}{2}$ for all $i \neq i_m$)}
$$

Hence, $R$ cannot satisfy Equation (5).

To prove our second claim, we will construct a ranking which has utility 1 and satisfies $(\gamma, \delta)$-equal representation. It suffices to choose any ranking $R$ which places $i_m$ in the first $n$ position satisfies constraint. By our earlier argument this ranking has a utility 1. Let $Z_j$ be the indicator random variable that the item in the $j$-th position in $R$ belongs to $G_1$. This implies that $\sum_{i \in G_1} \sum_{j=1}^{k} R_{ij} = \sum_{j=1}^{k} Z_j$ for all $k$. Further, by the choice of $P$, we have

$$\frac{k}{2} \leq \mathbb{E}\left[\sum_{j=1}^{k} Z_j\right] \leq \frac{k + 1}{2}. \quad \text{(50)}$$

Further, by Definition 3.2 we have that $Z_j$ is independent of $Z_k$ for any $j \neq k$. Let $\varepsilon_k := \sqrt{\frac{6}{k} \cdot \log \left(\frac{2n}{\delta}\right)}$. Using the above, we have

$$
\Pr\left[\sum_{i \in G_1} \sum_{j=1}^{k} R_{ij} \geq \frac{k + 1}{2} \cdot (1 + \varepsilon_k)\right] = \Pr\left[\sum_{j=1}^{k} Z_j \geq \frac{k + 1}{2} \cdot (1 + \varepsilon_k)\right] \\
\leq \Pr\left[\sum_{j=1}^{k} Z_j \geq \mathbb{E}\left[\sum_{j=1}^{k} Z_j\right] \cdot (1 + \varepsilon_k)\right] \quad \text{(Using Equation (50))} \\
\leq \exp\left(-\frac{\varepsilon_k^2 k}{6}\right) \quad \text{(Using the Chernoff’s bound, see [52])} \\
\leq \frac{\delta}{2n} \quad \text{(Using Equation (50))}
$$

Further, as $\gamma_k \geq \frac{k + 1}{k} \cdot (1 + \varepsilon_k)$, we get

$$
\Pr\left[\sum_{i \in G_1} \sum_{j=1}^{k} R_{ij} \geq \frac{k}{2} \cdot (1 + \gamma_k)\right] \leq \Pr\left[\sum_{i \in G_1} \sum_{j=1}^{k} R_{ij} \geq \frac{k + 1}{2} \cdot (1 + \varepsilon_k)\right] \leq \frac{\delta}{2n}.
$$
Further, considering $1 - Z_j$ and repeating a similar argument for $G_2$, we get

$$
\Pr \left[ \sum_{i \in G_2} \sum_{j=1}^{k} R_{ij} \geq \frac{k}{2} \cdot (1 + \varepsilon_k) \right] = \Pr \left[ \sum_{j=1}^{k} (1 - Z_j) \geq \frac{k}{2} \cdot (1 + \gamma_k) \right] 
$$

$$
\leq \Pr \left[ \sum_{j=1}^{k} (1 - Z_j) \geq \mathbb{E} \left[ \sum_{j=1}^{k} (1 - Z_j) \right] \cdot (1 + \gamma_k) \right] \quad \text{(Using Equation (50))}
$$

$$
\leq \exp \left( -\frac{\gamma^2}{3} \cdot \mathbb{E} \left[ \sum_{j=1}^{k} (1 - Z_j) \right] \right) \quad \text{(Using the Chernoff's bound, see [52])}
$$

$$
\leq \exp \left( -\frac{\gamma^2 (k - 1)}{6} \right) \quad \text{(Using Equation (50))}
$$

$$
\leq \frac{\delta}{2n}. \quad \text{(Using Equation (49))}
$$

By taking the union bound over all $k$, one can show that $R$ satisfies $(\gamma, \delta)$-equal representation. \hfill \Box

### E.7 Proof of Proposition E.11

**Proposition E.11.** There exist $p \in [0, 1]^m$ such that (4) is non-convex in $R$.

**Proof.** It suffices to specify $n$, $m$, $p$, $\varepsilon$, $\delta$, and two rankings $R_1$ and $R_2$ such that both $R_1$ and $R_2$ satisfy $(\varepsilon, \delta)$-equal representation, but $\frac{R_1 + R_2}{2}$ does not satisfy $(\varepsilon, \delta)$-equal representation.

Define $n := 2$, $m := 4$, and $\varepsilon := \left[ \frac{1}{4} \ 0 \right]^T$. Fix any $0 < \delta < \frac{1}{2}$. Define

$$
p := [1 \ 0 \ \delta \ 1 - \delta]^T.
$$

Let $R_1$ be the ranking that places items 1 and 3 in the first and second position, and $R_2$ be the ranking that places items 2 and 4 in the first and second position, i.e.,

$$
R_1 := \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \quad \text{and} \quad R_2 := \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.
$$

If $1 \in G_1$ and $3 \in G_2$, then $R_1$ places an equal number of items from $G_1$ and $G_2$ in the first two positions, and hence, satisfies equal representation. This event, happens with probability $p_1 (1 - p_3) = 1 - \delta$. Thus, $R_1$ satisfies $(0, \delta)$-equal representation, and hence, $(\varepsilon, \delta)$-equal representation. Replace item 1 and 3 with 2 and 4 and swap $G_1$ and $G_2$ in the above argument, to get that $R_2$ also satisfies $(\varepsilon, \delta)$-equal representation.

However, we claim that $\frac{R_1 + R_2}{2}$ does not satisfy $(\varepsilon, \delta)$-equal representation. Note that with probability $1, 1 \in G_1$ and $2 \in G_2$. If $3, 4 \in G_1$ or $3, 4 \in G_2$, then $\frac{R_1 + R_2}{2}$ violates the equal representation constraint on the top-2 positions by a multiplicative factor of $\frac{\gamma}{2}$. At least one of these events happens with probability $p_3 p_4 + (1 - p_3)(1 - p_4) = 2\delta (1 - \delta) > \delta$, as $\delta < \frac{1}{2}$. Thus, $\frac{R_1 + R_2}{2}$ does not satisfy $(\varepsilon, \delta)$-equal representation for the specified $\varepsilon := \left[ \frac{1}{4} \ 0 \right]^T$ and $\delta < \frac{1}{2}$. \hfill \Box

### E.8 Proof of Theorem E.12

In this section, we prove the following theorem.

**Theorem E.12.** Given $p \in [0, 1]^m$, $\delta \in (0, 1]$, $W \in \mathbb{R}_{\geq 0}^{m \times n}$, $\varepsilon \in [0, 1]^n$, and $V \geq 0$ it is NP-hard to decide if the value of Program (4) is at least $V$. 

35
Recall that constraint (52) is necessary and sufficient to satisfy \((\varepsilon, \delta)\)-equal representation, and hence, the value of (51) is the maximum utility of a ranking subject to satisfying \((\varepsilon, \delta)\)-equal representation.

\[
\max_{R \in \mathcal{R}} \langle R, W \rangle
\]

s.t. w.p. at least \(1 - \delta\) over draw of \(G_1, G_2\),

\[
\forall k \in [n], \forall \ell \in [2], \quad \sum_{i \in G_\ell} \sum_{j=1}^{k} R_{ij} \leq \frac{k}{2} \cdot (1 + \varepsilon_k).
\]  

We will show that the decision version of (51) is \(\text{NP}\)-hard.

**Theorem E.13.** Given \(L \geq 0, \delta \in [0, 1], \varepsilon \in [0, 1]^n, P \in [0, 1]^{m \times p}, \) and \(W \in \mathbb{R}^{m \times n}_{\geq 0}\) it is \(\text{NP}\)-hard to decide if the value of (51) is at least \(L\).

The proof of Theorem E.13 proceeds in two steps. In the first step, we reduce (53) to (51). In the second step, we prove that (53) is \(\text{NP}\)-hard because the \(\text{NP}\)-complete product partition problem reduces to (53). Together, the two steps imply the hardness of (51). The proof of the second step is inspired by the construction of [57] for the product knapsack problem, which is similar to (53).

**Step 1: Reduction from (53) to (51).** In this step, we will reduce the following problem to (51).

**Input:** \(L \geq 0, n \in [m], \delta \in [0, 1], U \in [0, \frac{n}{2}], v \in \mathbb{R}_m^m, \) and \(P \in [0, 1]^{m \times p}\)

**Decision problem:** Is the value of (53) at least \(L\)?

\[
\max_{S \subseteq [m]: |S| = n} \sum_{i \in S} v_i
\]

s.t. w.p. at least \(1 - \delta\) over draw of \(G_1, G_2\),

\[
|S \cap G_1| \leq U + \frac{n}{2} \quad \text{and} \quad |S \cap G_2| \leq U + \frac{n}{2}.
\]

**Reduction.** Given an instance of (53) we construct the following instance of (51):

\[
W := v1_n^\top,
\]

\[
\varepsilon_1 = \varepsilon_2 = \cdots = \varepsilon_{n-1} := \frac{2n}{k} - 1,
\]

\[
\varepsilon_n := \frac{2U}{n} - 1,
\]

where \(1_n := (1, \ldots, 1) \in \mathbb{R}^n\). The parameters \(L, \delta, \) and \(P\) are the same as the instance of (53).

The reduction from (53) to (51) is as follows: First solve (53) to obtain a ranking \(R\). Let \(S\) be the set of items \(R\) places in the top-\(n\) positions. Output \(S\). Clearly, this is a polynomial-time reduction. It remains to prove that it is sound and complete.

In our construction, Condition (54) implies that the utility of a ranking only depends on the set of \(n\) items it places in the top-\(n\) positions, and hence, any two rankings that place the same set of items in the top-\(n\) positions have the same utility. Condition (55) ensures that any ranking satisfies the constraints in the first \(n - 1\) positions with probability 1. This is because, for all \(k \in [n - 1], \frac{k}{2} (1 + \varepsilon_k) = n > k\). Thus, a ranking \(R\) is feasible for (51) if and only if it satisfies: With probability at least \(1 - \delta\) over draw of \(G_1, G_2\),

\[
\forall \ell \in [2], \quad \sum_{i \in G_\ell} \sum_{j=1}^{k} R_{ij} \leq \frac{n}{2} \cdot (1 + \varepsilon_n) = U + \frac{n}{2}.
\]

\(^4\)To be precise, we consider \(\varepsilon_1 = \varepsilon_2 = \cdots = \varepsilon_{n-1} := \min \{1, \frac{2n}{k} - 1\}\) and \(\varepsilon_n := \min \{1, \frac{2U}{n} - 1\}\).
Soundness and completeness. Fix any \( R \in \mathcal{R} \). Let \( S \) be the set of items \( R \) places in the top-\( n \) positions. It holds that

\[
\langle R, W \rangle = \sum_{i \in S} v_i.
\]

It remains to show that \( R \) is feasible for (51) if and only if \( S \) is feasible for (53). Due to conditions (55) and (56), \( R \) is feasible for (51) iff: With probability at least \( 1 - \delta \) over draw of \( G_1, G_2 \),

\[
\forall \ell \in [2], \sum_{i \in G_\ell} \sum_{j=1}^{k} R_{ij} \leq U + \frac{n}{2}.
\]

Since by the definition of \( S \), for all \( T \subseteq [m] \), \( \sum_{i \in T} \sum_{j=1}^{n} R_{ij} = |S \cap T| \), it follows that with probability \( 1 - \delta \) over draw of \( G_\ell \),

\[
\forall \ell \in [2], \sum_{i \in G_\ell} \sum_{j=1}^{k} R_{ij} \leq U + \frac{n}{2}.
\]

Thus, \( S \) is feasible for (53) if and only if \( R \) is feasible for (51). Thus, the reduction is sound and complete.

Step 2: Reduction from product partition problem to (53). We consider the following version of the product partition problem:

Cardinality constrained product partition problem (CPPP)

Input: \( a_1, a_2, \ldots, a_q \in \mathbb{Z}_{\geq 0} \) and \( \ell \in \{0, 1, \ldots, q\} \).

Decision problem: Is there a set \( S \subseteq [q] \) of size \( \ell \) such that

\[
\prod_{i \in S} a_i = \prod_{i \in [q] \setminus S} a_i.
\]

The usual product partition problem (PPP) does not require \( S \) to have size \( \ell \) and is known to be NP-complete. CPPP is clearly in NP. To see that CPPP is NP-complete, one can reduce PPP to CPPP: To see this, given an instance of PPP, construct \( q + 1 \) instances of CPPP, one for each value of \( \ell \in \{0, 1, \ldots, q\} \). Then, PPP is a ‘Yes’ instance if and only if at least one of the \( q + 1 \) CPPP instances in a ‘Yes’ instance. Thus, it follows that CPPP is also NP-complete.

Assumptions on CPPP instances without loss of generality. The decision problem for CPPP is simple for instances with \( \ell = 0 \), or with one or more of \( a_1, \ldots, a_q \) as 0. As all inputs are integral, without loss of generality, we assume that \( \ell \geq 1 \) and \( a_1, \ldots, a_q \geq 1 \). Note that if in an CPPP \( \sqrt[\ell]{a_1 \cdots a_q} \) is non-integral, then it is a ‘No’ instance. This can be verified in polynomial time, and hence, without loss of generality, we assume that \( \sqrt[\ell]{a_1 \cdots a_q} \) is integral.

Reduction from CPPP to (53). Given an instance of CPPP, we construct an instance of (53) with

\[
n := 2\ell, \quad m := q + \ell, \quad U := \ell - 1, \quad \text{and} \quad \delta := \left( \frac{1}{a_{\text{max}}} \right)^{\ell^2},
\]

where \( a_{\text{max}} := \max_{i \in [q]} a_i \). Further, define constants

\[
M := (\ell + 2) \cdot \sqrt[q]{a_1 \cdots a_q} \quad \text{and} \quad B := q \cdot \lceil M \log(a_{\text{max}}) \rceil + 1.
\]

We choose \( v \) so that the first \( q \) items correspond to the \( q \) numbers in the CPPP instance, and the next \( \ell \) items have a “high” value:

\[
\forall i \in [q], \quad v_i := \lceil M \log(a_i) \rceil,
\]

\[
\forall i \in [\ell], \quad v_{i+q} := L.
\]
Note that each of the last $\ell$ items has a value larger than the total value of the first $q$ items, i.e.,
\[
\forall i \in [\ell], \quad v_{i+q} = B > \sum_{j \in [q]} v_j. \tag{61}
\]
We choose $P$ so that for the first $q$ items $P_{i,1} \propto a_i^q$ and the next $\ell$ are in $G_{i}$ with probability 1:
\[
\forall i \in [q], \quad P_{i,1} := \left( \frac{a_i}{a_{\text{max}}} \right)^q \cdot \frac{1}{\sqrt{\prod_{i=1}^q a_i}} \quad \text{and} \quad P_{i,2} = 1 - P_{i,1},
\]
\[
\forall i \in [\ell], \quad P_{i+q,1} := 1 \quad \text{and} \quad P_{i+q,2} = 1 - P_{i+q,1}. \tag{62}
\]
Finally, let
\[
L := \ell B + \left\lceil \frac{M}{2} \sum_{i=1}^q \log(a_i) \right\rceil. \tag{64}
\]
The reduction from CPPP to (53) is as follows: First solve the constructed instance of (53) to get $S$. Then output $S\setminus Q$, where $Q := [\ell + q] \setminus [q]$ is the set of the last $\ell$ items.

Let $C \in \mathbb{Z}$ be the bit complexity of the input for the given instance of (53). To show that the reduction is polynomial time, it suffices to show that $L$ and $|M \log(a_{i_1})|, \ldots, |M \log(a_{i_q})|$ can be computed in poly($C$) time. Note that, $M \leq 2^{O(C)}$, and hence, to compute $|M \log(a_{i_1})|$ it suffices to compute $\log(a_i)$ up to $O(C)$ bits, which can be done in poly($C$) time. Similarly, to compute $L$ it suffices to compute $\sum_{i=1}^q \log(a_i)$ up to $O(C)$ bits, which can be done in poly($C$) time. Thus, the reduction is polynomial time.

The choice of $L$ and $v$ ensures that the following fact holds.

**Fact E.14.** If a set $S \subseteq [q]$ satisfies $\sum_{i \in S} v_i \geq L$ and $|S| = n$, then $S \supseteq Q$.

**Proof.** Suppose toward a contradiction that satisfies $\sum_{i \in S} v_i \geq L$ and $|S| = n$ but $S$ does not contain $Q$. Since $S = n = 2\ell$ Then,
\[
\sum_{i \in S} v_i = \sum_{i \in S \cap Q} v_i + \sum_{i \in S \setminus Q} v_i \leq |S \cap Q| \cdot \max_{i \in Q} v_i + \sum_{i \in [q] \setminus Q} v_i \quad \text{(Using $S \subseteq [q]$ and $v_i \geq 0$)}
\]
\[
< \lceil |S \cap Q| \cdot B \rceil + B \quad \text{(Using that $|S \cap Q| \leq |Q| - 1$ and $B > 0$)}
\]
\[
\leq L. \quad \text{(Using (64), $|Q| = \ell$, and $L = \ell B$)}
\]
\]

**Soundness.** Suppose $S$ is feasible for (53) and satisfies $\sum_{i \in S} v_i \geq L$. Due to (63), with probability 1, $G_1 \supseteq Q$. Hence, $G_2 \cap Q = \emptyset$. Thus,
\[
\sum_{i \in S} v_i \geq L \quad \text{and} \quad |S| = n \quad \text{(as $S$ is feasible for (53)), Fact E.14 implies that $S \supseteq Q$, hence $|S \setminus Q| = |S| - \ell$). Combining this with the above equation, we get that}
\[
\sum_{i \in S} v_i \geq L \quad \text{with probability 1,} \quad |S \cap G_2| = |(S \setminus Q) \cap G_2| \leq |S \setminus Q|.
\]
\[
\sum_{i \in S} v_i \geq L \quad \text{with probability 1,} \quad |S \cap G_2| \leq |S| - \ell \leq \ell. \quad \text{(Using that $|S| = n = 2\ell$)}
\]
\[
\sum_{i \in S} v_i \geq L \quad \text{with probability 1,} \quad |S \cap G_2| \leq |S| - \ell \leq \ell.
\]
\[
\sum_{i \in S} v_i \geq L \quad \text{with probability 1,} \quad |S \cap G_2| \leq |S| - \ell = \ell. \quad \text{(Using that $|S| = n = 2\ell$)}
\]
Since $U \geq 0,$

 \[ |S \cap G_2| \leq U + \ell. \]  \hfill (65)

S is feasible for (53) iff:

\[
\Pr_{G_1, G_2} \left( |S \cap G_1| \leq U + \ell \right) \quad \text{and} \quad |S \cap G_2| \leq U + \ell \geq 1 - \delta
\]

\[(66)\]

\[
\Pr_{G_1, G_2} \left( |S' \cap G_1| \leq U \right) \geq 1 - \delta
\]

\[
\Pr_{G_1, G_2} \left( |S' \cap G_1| > U \right) \leq \delta
\]

\[
\Pr_{G_1, G_2} \left( |S' \cap G_1| = n \right) \leq \delta
\]  

(Using that $U = n - 1$ and $|S'| = \ell$)

\[
\prod_{i \in S'} a_i \leq \prod_{i \in [q]} a_i.
\]

(Using that $\ell > 0, a_1, \ldots, a_q > 0,$ and $|S'| = \ell$)  \hfill (67)

Since $S$ is feasible for (53), it holds that

\[
\prod_{i \in S'} a_i \leq \prod_{i \in [q]} a_i.
\]

To show that $S'$ is feasible for CPPP, it remains to show that the above equation holds with equality.

Suppose toward a contradiction that $\prod_{i \in S'} a_i < \prod_{i \in [q]} a_i$. Then, because $\prod_{i \in [q]} a_i$ and $a_1, \ldots, a_q$ are integral

\[
\prod_{i \in S'} a_i \leq \prod_{i \in [q]} a_i - 1.
\]

Because $M \geq 0$, taking the logarithm we get

\[
M \sum_{i \in S'} \log a_i \leq M \log \left( \prod_{i \in [q]} a_i - 1 \right). \hfill (67)
\]

To upper bound the RHS, we will use the following fact:

**Fact E.15.** For all $x \geq 1$, \( \log x - \log (x - 1) \geq \frac{1}{x} \).

Using Fact E.15 with $x = \sqrt{\prod_{i \in [q]} a_i}$ (as $a_1, \ldots, a_q \geq 1$), we get

\[
\log \left( \sqrt{\prod_{i \in [q]} a_i} \right) - \log \left( \prod_{i \in [q]} a_i - 1 \right) \geq \frac{1}{\sqrt{\prod_{i \in [q]} a_i}}.
\]
Hence, by (58)

\[ M = (\ell + 2) \cdot \frac{\prod_{i \in [q]} a_i}{\log(\sqrt{\prod_{i \in [q]} a_i}) - \log(\sqrt{\prod_{i \in [q]} a_i - 1})}. \]

On rearranging, we get

\[ M \log(\sqrt{\prod_{i \in [q]} a_i - 1}) \leq M \log(\sqrt{\prod_{i \in [q]} a_i}) - \ell - 2. \]

Substituting this in (67), we get

\[ M \sum_{i \in S'} \log a_i \leq M \log(\sqrt{\prod_{i \in [q]} a_i}) - \ell - 2. \]

Since for all \( i \in S' \), \( v_i \leq M \log(a_i) + 1 \), it follows that

\[ \sum_{i \in S'} v_i \leq \frac{M}{2} \log(\prod_{i \in [q]} a_i) - 2 < \left\lfloor \frac{M}{2} \log(\prod_{i \in [q]} a_i) \right\rfloor. \] (68)

Thus,

\[ \sum_{i \in S} v_i = \sum_{i \in S' Q} v_i + \sum_{i \in S \setminus Q} v_i \]

\[ = \ell B + \sum_{i \in S'} v_i \quad \text{(Using that } S \supseteq Q \text{ and } S' := S \setminus Q) \]

\[ \leq \ell B + \left\lfloor M \log(\sqrt{\prod_{i \in [q]} a_i}) \right\rfloor \]

\[ = L. \]

This is a contradiction to \( \sum_{i \in S} v_i \geq L \).

**Completeness.** It suffices to show that if \( S' \) is feasible for the given instance of CPPP, then \( S := S' \cup Q \) is feasible for (53) and satisfies \( \sum_{i \in S} v_i \geq A \).

Due to (63), with probability 1, \( G_1 \supseteq Q \). Hence, \( G_2 \cap Q = \emptyset \). Thus,

\[ |S \cap G_2| = |(S \setminus Q) \cap G_2| \leq |S \setminus Q| = |S'| = \ell, \]

where the last equality holds as \( S' \) is feasible for the given instance of CPPP. This implies that (65) holds. Hence, by following the same arguments, (66) also holds. Thus, \( S := S' \cup Q \) is feasible for (53).

It remains to show that \( \sum_{i \in S} v_i \geq L \).

\[ \sum_{i \in S} v_i = \sum_{i \in Q} v_i + \sum_{i \in S'} v_i \quad \text{(Using that } S := S' \cup Q) \]

\[ = \ell B + \sum_{i \in S'} v_i \]

\[ \geq \ell B + \sum_{i \in S'} M \log a_i \]

\[ = \ell B + \frac{M}{2} \log(\prod_{i \in [q]} a_i) \quad \text{(Using that } \prod_{i \in S'} a_i = \prod_{i \in [q]} a_i) \]

\[ \geq A. \]
F Extension of theoretical results to position-weighted constraints

In this section, we extend Theorem 4.1 to position-weighted version of fairness constraints. In particular, given position-discounts

\[v_1 \geq v_2 \geq \cdots \geq v_n\]

and a matrix \(U \in \mathbb{Z}_{+}^{n \times p}\) the position-weighted fairness constraint requires a ranking \(R\) to satisfy:

\[\forall k \in [n], \ell \in [p], \sum_{i \in G_{\ell}} \sum_{j \in [k]} v_j R_{ij} \leq U_{k\ell}\]

for all \(k\) and \(\ell\). For these constraints, we consider the following analogue of \((\varepsilon, \delta, \nu)\)-constraints: A ranking \(R\) is said to satisfy \((\varepsilon, \delta, \nu)\)-constraint if with probability at least \(1 - \delta\) over the draw of \(G_1, \ldots, G_p\)

\[\forall k \in [n] \forall \ell \in [p], \sum_{i \in G_{\ell}} \sum_{j=1}^{k} v_j R_{ij} \leq U_{k\ell}(1 + \varepsilon_k).\] (69)

For these position-dependent constraints, our framework largely remains the same and is stated in Program (72). Compared to Program (7), the main difference is in the left-hand side of Program (71). We can prove the guarantees on the fairness and accuracy of the optimal solution of Program (72), under the additional assumption that, for a constant \(\psi > 0\), \(U\) satisfies that

\[\forall \ell \in [p], \forall k \in [n], U_{k\ell} \geq \psi k.\] (70)

The parameter \(\psi\) shows up in Equation (71).

Our Fair-Ranking Framework for Position-Dependent Constraints

**Input:** Matrices \(P \in [0, 1]^{m \times p}, W \in \mathbb{R}_{\geq 0}^{m \times n}, U \in \mathbb{R}^{n \times p}\)

**Parameters:** A constant \(c > 1\), a failure probability \(\delta \in (0, 1]\), and for each \(k \in [n]\), a relaxation parameter

\[\gamma_k := \frac{1}{\psi} \cdot \log \left( \frac{2np}{\delta} \right) \cdot \max_{\ell \in [p]} \sqrt{\frac{1}{U_{k\ell}}}.\] (71)

**Program:**

\[
\max_{R \in \mathcal{R}} (R, W), \\
\text{s.t. } \forall \ell \in [p] \forall k \in [n] \\
\sum_{i \in [m], j \in [k]} v_j P_{\ell i} R_{ij} \leq U_{k\ell} \left( 1 + \frac{2\sqrt{c - 1}}{2\sqrt{c}} \cdot \gamma_k \right). \] (73)

We prove the following guarantees on the fairness and accuracy of the optimal solution of Program (72).

**Theorem F.1.** Let \(\gamma \in \mathbb{R}^n\) be as defined in Equation (71). If the matrix \(U \in \mathbb{Z}_{+}^{n \times p}\) satisfies that for all \(\ell \in [p]\) and \(k \in [n]\), \(U_{k\ell} \geq \psi k\), then it is an optimization program Program (72), parameterized by a constant \(c\) and failure probability \(\delta\), such that for any \(c > 1\) and \(\delta \in (0, 1/2]\), its optimal solution satisfies \((c\gamma, \delta, \nu)\)-constraint and has a utility at least as large as the utility of any ranking satisfying \((c - \sqrt{c})\gamma, \delta, \nu)\)-constraint.

The proof of Theorem F.1 is analogous to the proof of Theorem 4.1. Here, we highlight the differences.

**Notation.** Recall that for each item \(i \in [m]\) and group \(\ell \in [p]\), let \(Z_{\ell i} \in \{0, 1\}\) is indicator random variable that \(Z_{\ell i} := 1(G_{\ell} \ni i)\).

The first change is in the definition of \(Z_{\#}(R, \ell, k)\). In particular, we need to define

\[Z_{\#}(R, \ell, k) = \sum_{i \in G_{\ell}} \sum_{j=1}^{k} v_j R_{ij}.\]

For the new definition of \(Z_{\#}\), we have following concentration result.
Lemma F.2. For any position \( k \in [n] \), group \( \ell \in [p] \), parameters \( \varepsilon \geq 0 \) and \( L, U \in \mathbb{R} \), and ranking \( R \in \mathcal{R} \), where \( R \) is possibly a random variable independent of \( \{Z_{i\ell}\}_{i}\), if \( P(R, \ell, k) \leq U \) or \( P(R, \ell, k) \geq L \) then the following equations hold respectively

\[
\Pr[Z_{\#}(R, \ell, k) < (1 + \varepsilon) U] \geq 1 - e^{-\frac{2U^2\varepsilon^2}{k}},
\]

\[
\Pr[Z_{\#}(R, \ell, k) > (1 - \varepsilon) L] \geq 1 - e^{-\frac{2L^2\varepsilon^2}{k}}.
\]

The proof of Lemma F.2 is identical to the proofs of Lemmas E.5 and E.6; the only change is the new definition of \( Z_{\#} \).

To prove Theorem F.1, it suffices to prove analogues of Propositions 6.1 and 6.2 for the new definition of \( Z_{\#} \). Their proofs change as follows:

**Proof of Proposition 6.1** The parameters in Equation (9) remain the same. Hence, following the same argument, Equation (10) holds. Now, we can prove Equation (12) as follows:

\[
\Pr[Z_{\#}(R, \ell, k) \geq U_{\ell k}(1 + \phi \gamma_k)] = \Pr[Z_{\#}(R, \ell, k) \geq U'(1 + \zeta)]
\]

(Using that \( U'(1 + \zeta) = U_{\ell k}(1 + \phi \gamma_k) \))

\[
\leq \exp \left(-\frac{2(U')^2 \zeta^2}{k}\right) \quad \text{(Using Lemma F.2)}
\]

\[
= \exp \left(-\frac{2(1 - \phi)^2 U_{\ell k}^2 \gamma_k^2}{k}\right) \quad \text{(Using Equation (9))}
\]

\[
\leq \exp \left(-2\psi(1 - \phi)^2 U_{\ell k}^2 \gamma_k^2\right) \quad \text{(Using that } U_{\ell k} \geq \psi k)\]

\[
\leq \frac{\delta}{2np} \quad \text{(Using Equation (71))} \quad \text{(74)}
\]

Proposition 6.1 follows by replacing Equation (12) by Equation (74) in the rest of its proof.

**Proof of Proposition 6.2** The parameters in Equation (13) remain the same. Now, we can prove \( \Pr[Z_{\#}(R', k, \ell) \leq U_{k\ell}] < 1 - \delta \) as follows:

\[
\Pr[Z_{\#}(R', k, \ell) \leq U_{k\ell}] = \Pr[Z_{\#}(R', k, \ell) \leq L' \cdot (1 - \zeta)]
\]

(Using that \( L'(1 - \zeta) = U_{k\ell}(1 + b \gamma_k) \))

\[
\leq \exp \left(-\frac{2(L')^2 \zeta^2}{k}\right) \quad \text{(Using Lemma F.2)}
\]

\[
= \exp \left(-\frac{2(\phi - b)^2 \gamma_k^2 U_{k\ell}^2}{k}\right) \quad \text{(Using Equation (13))}
\]

\[
\leq \exp \left(-2\psi(\phi - b)^2 \gamma_k^2 U_{k\ell}\right) \quad \text{(Using that } U_{k\ell} \geq \psi k)\]

\[
< \frac{\delta}{2np} \quad \text{(Using Equation (71) and Equation (13))} \quad \text{(75)}
\]

\[
< 1 - \delta. \quad \text{(Using that } \delta < \frac{1}{2} \text{ and } n \geq 1) \quad \text{(76)}
\]

The rest of the proof is identical.

**G Implementation details and additional empirical results**

In this section, we present the implementation details of our simulations (Supplementary Materials G.1 and G.1.1), give additional plots for the simulation in Section 5 (Supplementary Material G.2), and additional simulations that use weighted-selection risk as the fairness metric or vary the amount of noise in the data (Supplementary Materials G.3 and G.3.2).
Code. The code for all simulations is available at https://github.com/AnayMehrotra/FairRankingWithNoisyAttributes.

G.1 Implementation details

In this section, we give implementation details of our algorithm and baselines.

- **NResilient**: We implement NResilient in Python 3 and use the Gurobi optimization library to solve the linear program in Step 1 of Algorithm 1. We state complete pseudocode of NResilient’s implementation as Algorithm 2.

- **SJ**: This is [61]’s algorithm. SJ (1) solves a linear program whose objective encodes the utility of the ranking and whose constraints capture the fairness constraints, and (2) decomposes the solution as a convex combination of the rankings, and uses this convex combination to generate rankings (see [61, Section 3.4]).

  - More precisely, [61]’s approach works for any linear constraint on the ranking (see the last equation in [61, Section 3.3]). For instance, as noted in [61, Section 3.3], their approach can satisfy multiple constraints of the form: Given any vectors \( f \in \mathbb{R}^m \), \( g \in \mathbb{R}^n \), and \( h \in \mathbb{R} \), require the ranking \( R \in \{0, 1\}^{m \times n} \) to satisfy \( f^T R g = h \). By introducing a class variable \( s \) with constraint \( s \geq 0 \), their approach extends to constraints of the form \( f^T R g \leq h \).

  - These are sufficient to encode the constraint in Definition 2.2: For any \( k \) and \( \ell \), define

    \[
    \forall i \in [m], \quad f_i = \mathbb{I}[i \in G_\ell], \\
    \forall j \in [n], \quad g_j = \mathbb{I}[j \leq k], \\
    h = U_{k\ell}.
    \]

  - The constraint \( f^T R g \leq h \) with the above values is equivalent to the upper bound specified by \( U_{k\ell} \) in Definition 3.2. Repeating this construction for each \( k \) and \( \ell \), we get a set of constraints that capture the fairness constraints specified by \( U \).

- **CSV**: This is the greedy algorithm from [18, Theorem 3.3]. [18] do not provide an implementation of CSV, we implement their algorithm in Python3 with NumPy.

- **GAK**: This is the Det-Greedy algorithm of [27]. [27] do not provide an implementation of GAK, we implement GAK in Python3 with NumPy.

- **MC**: This first uses the algorithm of [48] to compute a subset \( S \) and then selects a ranking of these items that maximize the utility (in the simulations this amounts to sorting items by \( w_i \)). We used the implementation of [48]’s algorithm available at https://github.com/AnayMehrotra/Noisy-Fair-Subset-Selection and use Python3’s in-built sorting function to generate the ranking. [48]’s algorithm takes \( P \) and parameters \( U \) specifying upper bound constraints as input.

- **Uncons**: This is the baseline that outputs the ranking with the maximum utility. In the simulation, this amounts to sorting all items in decreasing order of \( w_i \) and outputting the ranking with the first \( n \) items (in that order). We implement Uncons in Python3 with NumPy.

**Computational resources used.** All simulations were run on a t3.xlarge instance with 4 vCPUs and 16Gb RAM, on Amazon’s Elastic Compute Cloud (EC2).

G.1.1 Pre-processing details of the simulation with image data

In this section, we present additional preprocessing details to estimate \( \hat{P} \) in the simulation with the Occupations dataset presented in Section 5.
Algorithm 2 Pseudo-code of the implementation of NResilient

Require: Matrices \( P \in [0, 1]^{m \times p} \), \( W \in \mathbb{R}_{\geq 0}^{m \times n} \), \( U \in \mathbb{R}^{n \times p} \)
Ensure: A ranking \( R \in \mathcal{R} \)
Parameters: Constant \( c > 1 \), failure probability \( \delta \in (0, 1) \), and for each \( k \in [n] \), relaxation parameter \( \gamma_k > 0 \)
1: Compute a solution \( R_F \) to the standard linear programming relaxation of Program (72)
   \( \triangleright \) In the implementation, we use the Gurobi optimization library in Python 3 to compute \( R_F \)
2: Compute rankings \( R_1, R_2, \ldots, R_\Delta \in \mathcal{R} \) and coefficients \( \alpha_1 \geq \alpha_2 \geq \cdots \geq \alpha_\Delta \in [0, 1] \) such that
   \[ R_F = \sum_{i=1}^\Delta \alpha_i R_i. \]
   \( \triangleright \) In the implementation, we use the code available at https://github.com/jfinkels/birkhoff to compute this decomposition. This code implements an algorithm to compute the Birkhoff-von Neumann decomposition. The value of \( \Delta \) does not need to be specified: It is the number of rankings output by the algorithm to compute the Birkhoff-von Neumann decomposition.
3: Construct matchings \( M_1, \ldots, M_\Delta \) corresponding to each ranking \( R_1, \ldots, R_\Delta \) such that, for each \( t \in [\Delta] \), \( M_t \) has an edge between item \( i \) and position \( j \) if \( i \) appears in position \( j \) in \( R_t \)
4: Initialize \( N_1 = M_1 \)
5: for \( t = 1, 2, \ldots, \Delta - 1 \) do
6: \( N_{t+1} = \text{Merge}(\alpha_{t+1}, M_{t+1}, \sum_{\ell=t}^{\ell=t} t, M_t, N_t) \)
7: end for
8: Construct a ranking \( R \) corresponding to \( N_\Delta \): Item \( i \) appears at position \( j \) in \( R \) if and only if, \( i \) and \( j \) are matched in \( N_\Delta \)
9: return \( R \)

Algorithm 3 Merge procedure used by Algorithm 2

Require: Numbers \( 0 < \alpha, \beta \leq 1 \) and matchings \( M \) and \( N \)
Ensure: A matching \( K \)
Parameters: A constant \( t \) (Set to \( t := 100 \) in the implementation)
1: while \( M \neq N \) do
2: \( P = \text{getPaths}(M, N, t) \)
3: \( P' = \text{getPaths}(M, N, t) \)
4: Set \( \rho := \frac{t+1}{|P|} \) and \( \sigma := \frac{t}{|P'|} \), and \( p = \frac{\alpha \rho}{\alpha \rho + \beta \sigma} \)
5: Draw variables \( v, u \) u.a.r. from \([0, 1]\]
6: if \( u \leq \frac{\alpha \rho}{\alpha \rho + \beta \sigma} \) then
7: Draw \( i \) u.a.r. from \([|P|]\) and set \( M = M \Delta P_i \)
8: else
9: Draw \( i \) u.a.r. from \([|P'|]\) and set \( N = N \Delta P'_i \)
10: end if
11: end while
12: return \( K := M \)

Estimating \( \hat{P} \). We begin by removing all images with gender label NA; this leaves 5,825 images (out of 9,600). On the remaining images, we use an off-the-shelf face-detector \([1]\) to extract the faces of the people from the images and remove all images where the face-detector did not detect a face; this leaves 4,494 the images. We use a CNN-based gender classifier \([59]\) on the detected faces to predict the apparent gender of the depicted individuals. For each image \( i \), the classifier outputs a gender (coded as male and female) and an uncalibrated confidence score \( c_i \in [0, 1] \). We take the set of uncalibrated confidence scores \( \{c_i \in [0, 1]\} \) and calibrate them by first binning them, then computing the distribution of gender labels (provided in the dataset) for each bin. For each image \( i \), we set \( \hat{P}_{ci} \) (respectively \( \hat{P}_{ci} \)) equal to the fraction of images in the same bin as \( i \) whose gender label is female (respectively male). We perform this calibration once and on all occupations and, then, use it for a subset of occupations.
We observe that the rankings output by Clean-Fair Algorithm 4 getPaths procedure used by Algorithm 3 (up to standard errors) achieved fairness vs utility trade-off compared to baselines. For example, in P for 15:

Let the cycle formed by 17:

If 18:

end for

13: end for

14: else

end if

19: Set 20: Set

21: Set

22: return

Algorithm 4 getPaths procedure used by Algorithm 3

Require: Matchings M and N and a parameter t ≥ 1
Ensure: A set of paths P
1: Set P = ∅
2: if |MΔN| ≤ 2t then
3: Construct t paths p_1, . . . , p_t, where p_i = MΔN for each i
4: Let N\M := \{v_2, . . . , v_n\}
5: For each i ∈ [t], remove v_i from p_i
6: Set P := \{p_1, . . . , p_t\}
7: else if MΔN is a path then
8: Let the path formed by MΔN be (v_1, . . . , v_n)
9: for i = 1, 2, . . . , |MΔN| do
10: If v_i ∈ N set ℓ = 1 else set ℓ = 0
11: Set D := \{v_{i+2tk} : k ∈ N, ℓ + 2tk ≤ |MΔN|\}
12: Set P = P ∪ \{(MΔN)\}D
13: end for
14: else
15: Let the cycle formed by MΔN be (v_1, . . . , v_n)
16: for i = 1, 2, . . . , |MΔN| do
17: If v_i ∈ M: continue
18: S := \{v_{i(4j+1)}|MΔN| : j = 0, 1, . . . , 2t - 1\}
19: Set P = P ∪ S
20: end for
21: end if
22: return K := M

G.2 Further discussion and plots for simulations from Section 5

Illustrating the fairness vs. utility trade-off. In our empirical results, we use fairness metrics such as weighted risk-difference (Section 5) and weighted selection-lift (Supplementary Material G.3) to measure the algorithms’ achieved fairness. We do not use the parameter φ to measure fairness because the output of algorithms may have lower fairness than specified by φ. Figures 2, 8 and 10 plot utility vs. weighted risk-difference and Figures 14(b), 15(b) and 16(b) plot utility vs. weighted selection-lift (SL) for the simulations in Section 5. They show that NResilient better or similar (up to standard errors) achieved fairness vs utility trade-off compared to baselines. For example, in Figure 15(b) to achieve SL= 0.55 use Figure 15(a) to choose φ = 1.19 for NResilient and φ = 1.15 for CSV or SJ. For these values of φ, NResilient has 2% higher utility than CSV and SJ.

Comparison to baseline which has access to accurate protected attributes. Let Clean-Fair be the algorithm that, given utilities and accurate protected attributes, outputs the ranking with the maximum utility subject to satisfying equal representation constraint. Note that Clean-Fair can only be run in the ideal scenario where one has access to accurate protected attributes. We repeated the simulations in Section 5 and, for each of them, also measured the utility and fairness of Clean-Fair. We observe that the rankings output by Clean-Fair have a RD close to 1 (>0.99), this is expected because Clean-Fair has access to the clean protected attributes. We observe that the ranking output by NResilient (for any parameter 0 ≤ φ ≤ 1, specifying the fairness constraints for NResilient) has a utility that is at most 2%, 10%, and 4% smaller than that the ranking output by Clean-Fair.

RD of Uncons. Uncons’s RD and utility does not vary with φ because it does not take φ as input. Note that, Uncons also does not take the protected groups or P as input.

Plots with a small number of iterations. Figures 11 to 13 present results from simulations in Section 5 with 25, 50, and 100 iterations; compared to 500 or 1000 iterations in Figures 1 to 3. We observe that:

- the error bars for both utility and fairness (w.r.t. RD) are a larger (up to 0.025 compared to at most 0.0125 with 500/1000 iterations).
- the mean utilities and fairness (w.r.t. RD) of all algorithms at all values of φ are additively within 0.05 of their corresponding values in Figures 1 to 3.
Figure 4: Simulation on synthetic data with different values of $n$. The details appear in Supplementary Material G.2.

Moreover, the relative order of the algorithms with respect to both their fairness (w.r.t. RD) and utility is the same as in Figures 1 to 3 for all $\phi$.

**Plots with different values of $n$.** Figures 4 to 6 plot the RD and utilities (NDCG) with $n \in \{10, 30, 50\}$ in the simulations from Section 5; compared to $n = 25$ in Figures 1 to 3. We observe that the best RD attained by NResilient increases with $n$: Increasing $n$ from 10 to 30, increases RD from 0.76 to 0.85 with the synthetic data, from 0.75 to 0.84 with the real-world image data, and from 0.61 to 0.71 with the real-world name data (see Figures 4 to 6). Further, in all simulations, NResilient’s maximum RD is 2% to 8% higher than that of the baselines (see Figures 4 to 6). One exception is the simulation with real-world image data and $n = 10$. In this simulation, NResilient’s best RD is equal to GAK’s best RD. Both of them have > 6% higher best RD than any other algorithm. (See Figure 5.)

Figure 5: Simulation on image data with different values of $n$. The details appear in Supplementary Material G.2.

Figure 6: Simulation on real-world name data with different values of $n$. The details appear in Supplementary Material G.2.

**Empirical results with real-world name dataset and overlapping groups.** We present a variant of the simulation in Figure 3 that considers four overlapping groups: The sets of all women players, all male players, all non-White players, and all White players. In contrast, the simulation in Figure 3 uses four disjoint groups: The sets of non-White non-men players, White non-men players, non-White men players, and White men players.

**Setup.** The same setup as the simulation in Figure 3. The only difference is in estimating $\hat{P}$: For each $i$, we estimate $\hat{P}$ as:

$$\hat{P}_{i,\text{women}} = p_{\text{women}}(i),$$

$$\hat{P}_{i,\text{non-white}} = p_{\text{non-white}}(i),$$

$$\hat{P}_{i,\text{men}} = 1 - p_{\text{women}}(i),$$

$$\hat{P}_{i,\text{white}} = 1 - p_{\text{non-white}}(i).$$

Where $p_{\text{women}}(i)$ and $p_{\text{non-white}}(i)$ are values output by Genderize API and EthniColr Library that estimate the probability that player $i$ is labeled as a women and non-white respectively. (CSV and GAK require protected groups to be disjoint and, hence, are not applicable to this simulation.)
Figure 7: Simulation with the real-world name data and overlapping groups. The details appear in Supplementary Material [G2].

**Observations.** Figure 7 plots RD and utilities (NDCG) averaged over 200 iterations. The results are similar to the corresponding simulation on the same data with disjoint groups. In particular, compared to other baselines, **NResilient** achieves the highest RD. The maximum RD of **NResilient** in this simulation is 0.64 compared to 0.67 in Figure 3. **SJ** achieves the next highest RD followed by **MC** as in Figure 3.

Figure 8: Synthetic Data: Nonuniform Error Rate. This simulation considers synthetic data where imputed socially-salient attributes have a higher false-discovery rate for one group compared to the other. We vary the fairness constraint from $\phi$ from 2 (less fair) to 1 (more fair) and observe the weighted risk-difference (weighted risk-difference) of different algorithms. The y-axis plots utility and x-axis shows weighted risk-difference (Note that the values decrease toward the right). Error bars denote the error of the mean.

Figure 9: Real-world image data. This simulation considers images-search results which are known to overrepresent the stereotypical gender [38]. Given relevant non-gender labeled images and their utilities, our goal is to generate a high-utility gender-balanced ranking. We estimate $P$ using an off-the-shelf ML-classifier and vary $\phi$ from $p = 2$ (less fair) to 1 (more fair). In the first subfigure, the y-axis plots weighted risk-difference and x-axis shows $\phi$ (Note that the values decrease toward the right). Error bars show the error of the mean.

G.3 Additional empirical results

G.3.1 Empirical results with weighted selection-lift

In this section, we present empirical results with the weighted selection-lift fairness metric (Figures 14 to 16). Weighted selection-lift is a position-weighted version of the standard selection-difference metric. Like weighted risk-difference, it also measures the extent to which a ranking violates equal representation. The weighted selection-lift of a ranking $R$ is:

$$
\frac{1}{Z} \sum_{k=5,10,\ldots} \frac{\log k}{\epsilon \min_{q \in [p]} \left( \frac{\sum_{i \in G_q, j \in [k]} R_{ij}}{\sum_{i \in G_q, j \in [k]} R_{ij}} \right)}
$$

Where $G$ denotes the ground-truth protected groups and $Z$ is a constant so that RD has range $[0, 1]$. Here, a value of 1 is most fair and 0 is least fair.
Figure 10: Real-World Name Data: Intersectional Attributes. This simulation considers two socially-salient attributes, gender and race, and our goal is to ensure equal representation across the four intersectional socially-salient groups (non-White non-men, White non-men, non-White men, and White men). We estimate $P$ from the full names using public APIs and libraries. We vary $\phi$ from $p = 4$ (less fair) to 1 (more fair) and observe weighted risk-difference of all algorithms. The $y$-axis plots utility and $x$-axis shows weighted risk-difference (Note that the values decrease toward the right). Error bars represent the error of the mean.

Figure 11: Simulations on synthetic data from Section 5 with 25, 50, and 100 iterations. The details appear in Supplementary Material G.2.

Figure 12: Simulations on image data from Section 5 with 25, 50, and 100 iterations. The details appear in Supplementary Material G.2.

Figure 13: Simulations on real-world name data from Section 5 with 25, 50, and 100 iterations. The details appear in Supplementary Material G.2.

G.3.2 Empirical results with varying amount of noise

In this section, we present a simulation which uses the randomized response mechanism to generate noisy protected attributes and compares the performance of algorithms at varying noise levels.

**Data.** We use the Occupation images data [15]. We refer the reader to Section 5 for a discussion of the data.

**Setup.** We fix equal representation constraints ($\phi = 1$) and consider the same protected groups as the simulation with the same data in Section 5. We vary the noise level $0 \leq \eta \leq \frac{1}{2}$. For each $\eta$, we construct noisy attributes by mislabeling true protected attribute with probability $\eta$. Here, $P$ is specified by $\eta$ as explained in Remark A.1. Specifically, if $N_1$ and $N_2$ be the noisy versions of true
Figure 14: Synthetic Data (Weighted Selection Lift): Nonuniform Error Rate. This simulation considers synthetic data where imputed socially-salient attributes have a higher false-discovery rate for one group compared to the other. We vary the fairness constraint from $\phi$ from 2 (less fair) to 1 (more fair) and observe the weighted risk-difference (weighted risk-difference) of different algorithms. In the first sub-figure, the $y$-axis plots weighted selection-lift and $x$-axis shows $\phi$. In the second sub-figure, the $y$-axis plots utility and $x$-axis shows weighted selection-lift. Error bars represent the error of the mean.

Figure 15: Real-world image data. This simulation considers images-search results which are known to overrepresent the stereotypical gender [38]. Given relevant non-gender labeled images and their utilities, our goal is to generate a high-utility gender-balanced ranking. We estimate $P$ using an off-the-shelf ML-classifier and vary $\phi$ from $p = 2$ (less fair) to 1 (more fair). In the first sub-figure, the $y$-axis plots weighted selection-lift and $x$-axis shows $\phi$. In the second sub-figure, the $y$-axis plots utility and $x$-axis shows weighted selection-lift. Error bars represent the error of the mean.

Figure 16: Real-World Name Data: Intersectional Attributes. This simulation considers two socially-salient attributes, gender and race, and our goal is to ensure equal representation across the four intersectional socially-salient groups (non-White non-men, White non-men, non-White men, and White men). We estimate $P$ from the full names using public APIs and libraries. We vary $\phi$ from $p = 4$ (less fair) to 1 (more fair) and observe RD of all algorithms. In the first sub-figure, the $y$-axis plots weighted selection-lift and $x$-axis shows $\phi$. In the second sub-figure, the $y$-axis plots utility and $x$-axis shows weighted selection-lift. Error bars represent the error of the mean.
protected groups $G_1$ and $G_2$ (corresponding to the “flipped” protected attributes), then we set: For each item $i \in N_1$,

$$\tilde{P}_{i1} = (1 - \eta) \cdot \frac{|G_1|}{|N_1|} \quad \text{and} \quad \tilde{P}_{i2} = 1 - \tilde{P}_{i1}.$$ 

For items in $N_2$, replace $\tilde{P}_{i1}$, $\tilde{P}_{i2}$, $G_1$, and $N_1$ with $\tilde{P}_{i2}$, $\tilde{P}_{i1}$, $G_2$, and $N_2$. We do not have access to $G_1$ (and, hence, $|G_1|$), and in the above expression we estimate $|G_1|$ by $\alpha_1 := \frac{(1 - \eta)}{2} \cdot |N_1|$. This is because $\alpha_1$ can be shown to be concentrated around $|G_1|$.

Like the simulations in Section 3.3 CSV, GAK, and SJ are given the noisy attributes (as they require) and NResilient and MC are given $\tilde{P}$ (computed above).

**Observations.** See Figure 17 for RD and utilities (NDCG) averaged over 100 iterations. We observe that for each $\eta \geq 0.1$, NResilient’s RD is $>6.8\%$ better than any baseline (Figure 17(a)) and its utility is $<3\%$ smaller than the baseline (CSV) with best RD (Figure 17(b)). At $\eta = 0$, NResilient 3.3\% lower RD than CSV, GAK, and SJ and the same utility as them.

Note that in Figures 17(a) and 17(b) the plots of CSV, GAK, and SJ overlap. This is consistent with the other simulations where CSV, GAK, and SJ have the same RD and utility at $\phi = 1$.

**G.3.3 Empirical results with proportional representation constraints**

In this section, we present variants of the simulations in Figures 1 to 3 that use proportional representation fairness constraints. To measure the deviation of a ranking from proportional representation, we consider an adaptation of weighted risk-difference metric, Prop-RD. Prop-RD of a ranking $R$ is

$$1 - \frac{1}{Z} \sum_{k=5,10,...} \frac{1}{\log k} \max_{\ell,q} |\tilde{P}_{\ell q}\cdot \sum_{i \in G_{\ell}, j \in [k]} R_{ij} - \frac{n}{|G_{\ell}|} \cdot \sum_{i \in G_{\ell}, j \in [k]} R_{ij}|.$$ 

(77)

Where $G$ denotes the ground-truth protected groups and $Z$ is a constant so that RD has range $[0, 1]$. Here, Prop-RD $= 1$ is most fair and Prop-RD $= 0$ is least fair.

**Setup.** The setup of the simulations is identical to the simulations in Figures 1 to 3 except that, given $\phi \geq 1$, the upper bounds are set to $U_{k \ell} := \phi \cdot \frac{|G_{\ell}|}{n}$, $k$ for each $k \in [n]$ and $\ell \in [p]$.

**Observations.** Figure 18 presents the values of Prop-RD averaged over 50 iterations. We observe that, relative to the baselines, NResilient’s performance is similar to Figures 1 to 3. In particular, in all simulations, NResilient achieves a higher value of the fairness metric than any baselines, as in Figures 1 to 3. Further, in the simulation with the real-world image data, NResilient has a better
fairness-utility trade-off than all baselines, as in Figure 2. One difference is that, with the synthetic data, the value of the fairness metric achieved by NResilient can be non-monotonous in $\phi$, whereas it is increasing in $\phi$ in Figure 1 (see Figure 18).

Figure 18: Simulations with proportional representation constraints and variant of RD for proportional representation constraints. The details appear in Supplementary Material G.3.3.

G.3.4 Empirical results with varying false-discovery rates

In this section, we present a variant of the simulation in Figure 1. This simulation varies the difference in false-discovery rates (FDRs) of the attributes inferred from $P$ for the groups.

**Synthetic data.** We generate utilities $w_1, w_2, \ldots, w_m$ by drawing $w_i$ is independently from the uniform distribution over $[0, 1]$ for each $1 \leq i \leq m$. Fix $\mu_1 := 1 - \frac{1}{20}, \mu_2 := \frac{1}{2} - \frac{1}{20}, \sigma_1 := \frac{1}{50}$, and $\sigma_2 := \frac{1}{10}$. Given a parameter $0 \leq \tau \leq 1$, controlling the FDRs of the two groups, we construct $P$ as follows: For each $i$, with probability 0.6, $P_{i1}$ is drawn from $N((1 - \tau) \cdot \mu_1 + \tau, (1 - \tau) \cdot \sigma_1)$ and otherwise $P_{i1}$ is drawn from $N((1 - \tau) \cdot \mu_2 + \tau \cdot 0, (1 - \tau) \cdot \sigma_2)$.

We set $P_{i2} := 1 - P_{i1}$ for each $i$. This ensures that, with high probability,

$$|G_1| = 0.6n \pm o_n(1) \quad \text{and} \quad |G_2| = 0.4n \pm o_n(1)$$

Let FDR$_1(\tau)$ and FDR$_2(\tau)$ be the false-positive rates of attributes inferred from $P$ on groups $G_1$ and $G_2$ for a given $\tau$. Let $\Delta(\tau) := \text{FDR}_2(\tau) - \text{FDR}_1(\tau)$. We have $\Delta(0) = 0.4$, $\Delta$ decreases with $\tau$, and $\Delta(1) = 0$.

**Setup.** The setup is identical the simulation in Figure 1 except that we use the above synthetic data. We consider three values $\tau_1, \tau_2$, and $\tau_3$ of $\tau$ such that $\Delta(\tau_1) = 20\%$, $\Delta(\tau_2) = 20\%$, and $\Delta(\tau_3) = 20\%$. (For comparison, the FDRs of the two groups differ by 30% for the simulation in Figure 1)

**Observations.** See Figure 19 for RD averaged over 50 iterations. We observe that the difference between the best RD of NResilient those of SJ and CSV decreases with $\Delta$: At $\Delta = 20\%$, 10%, 5%, NResilient’s RD is 12%, 4%, and 0% higher than SJ’s and CSV’s RD respectively.

Figure 19: Simulation on synthetic data where the minority group’s FDR is $\Delta = 5\%$, 10%, 20% smaller than the majority’s FDR. The details appear in Supplementary Material G.3.4.
G.3.5 Empirical results with a large number of groups

In this section, we present simulations on synthetic datasets with 4, 6, 8, and 10 protected groups. For simplicity, all groups have equal sizes. In particular, we construct variants of the synthetic dataset in Section 5 so that the false-discovery rates of the attributes inferred from the matrix $P$ on the groups are spread at equal intervals in the interval $[10\%, 40\%]$. For instance, for $p = 4$, the FDRs of the four groups are 10%, 20%, 30%, and 40% respectively.

**Synthetic data.** We generate utilities $w_1, w_2, \ldots, w_m$ by drawing $w_i$ independently from the uniform distribution over $[0, 1]$ for each $1 \leq i \leq m$. Fix $\mu_1 := 1 - \frac{1}{20}$, $\mu_2 := \frac{1}{2} + \frac{1}{20}$, $\sigma_1 := \frac{1}{50}$, and $\sigma_2 := \frac{1}{10}$. For each group $G_\ell$, there is a parameter $0 \leq \tau_\ell \leq 1$, that controls the corresponding FDR. We construct $P$ as follows: For each $\ell$ and $i \in G_\ell$,

- $P_{i1}$ is iid from $\mathcal{N}((1 - \tau) \cdot \mu_1 + \tau \cdot \mu_2, (1 - \tau) \cdot \sigma_1 + \tau \cdot \sigma_2)$.
- $P_{i\ell} := 1 - P_{i1}$ where $z$ is drawn uniformly at random from $[p] \setminus \{\ell\}$
- $P_{ij} = 0$ for each $j \in [p] \setminus \{\ell, z\}$.

Let $\Delta(\tau)$ be the FDR of $G_\ell$ when $\tau_\ell = \tau$. (By construction, this function is independent of $\ell$.)

**Setup.** The setup is identical the simulation in Figure 1 except that we use the above synthetic data to generate $w$ and $P$. We vary $p \in \{4, 6, 8, 10\}$. For each $p$, we fix $\tau_\ell$ such that $\Delta(\tau_\ell) := 10\% + \frac{\ell - 1}{p} \cdot 30\%$ (for each $\ell \in [p]$).

**Observation.** Figure 20 plots RD averaged over 50 iterations. We observe that NResilient has a better or similar (within 1%) utility and RD compared to the best performing baseline at all values of $\phi$.

![Simulation on synthetic data with four, six, eight, and ten groups. The details appear in Supplementary Material G.3.5.](image)
