The nonconsensus opinion model (NCO) introduced recently by Shao et al., [Phys. Rev. Lett. 103, 018701 (2009)] is solved exactly on the line. Although, as expected, the model exhibits no phase transition in one dimension, its study is interesting because of the possible connection with invasion percolation with trapping. The system evolves exponentially fast to the steady-state, rapidly developing long-range correlations: The average cluster size in the steady state scales as the square of the initial cluster size, of the (uncorrelated) initial state. We also discuss briefly the NCO model on Bethe lattices, arguing that its phase transition diagram is different than that of regular percolation.

I. INTRODUCTION

A Nonconsensus Opinion model (NCO) has been introduced recently \cite{1} where each node in a graph can be in one of two states (representing opinions). At each time step each node adopts the state agreeing with the majority of the nodes in its neighborhood, consisting of the node itself and its nearest neighbors. In the event of a tie, the node retains its original state \cite{2}. The NCO model is thus similar to the majority-voter model, but where self-opinion counts. This difference is sufficient to ensure survival of the minority opinion, in the steady state \cite{1}. In \cite{1} a conjecture was made that the NCO model and invasion percolation with trapping (TIP) \cite{3} are in the same universality class, and this was well supported by convincing numerical evidence. As opposed to invasion percolation \textit{without} trapping, which is known to be in the same universality class as regular percolation, TIP is much less well understood \cite{3}. The following exact analysis of the NCO model, even though limited to the simplest case of one dimension, is therefore interesting not only on its own right, but also because of the possible connection with TIP. In addition, we discuss the phase transition diagram of the NCO model on Bethe lattices, finding a rich three-phase diagram, reminiscent of regular percolation in nonamenable \textit{one-ended} graphs. Models similar to the NCO have been considered in the context of social studies \cite{4}.

II. THE NCO MODEL IN 1D

In the following we will specialize to the evolution of the NCO model on the infinite line. Each lattice site can be either empty (\textcircled{0}) or occupied (\textcircled{1}). The initial state is completely random, with a fraction $p_0 = p$ of occupied sites, and $q_0 = 1 - p \equiv q$ empty sites. At each time step all of the sites get updated simultaneously according to the NCO rule: the new state of each site agrees with the majority of the states of the site’s neighborhood, consisting of the site itself and its two nearest neighbors. Thus, an occupied site remains occupied if at least one of its neighbors is occupied, but becomes empty in the next time step if both its neighbors are empty. An empty site remains empty if at least one neighbor is empty, and becomes occupied if both neighbors are occupied. It is easy then to predict the density of occupied and empty sites after the first step:

$$p_1 = p(1 - q^2) + q p^2 = 3 p^2 - 2 p^3, \quad q_1 = 3 q^2 - 2 q^3. \quad (1)$$

After this first step, the initially random state of the system develops correlations and one can no longer apply the same reasoning to predict the state of the system in subsequent steps. Indeed, ignoring correlations and iterating the mapping \cite{1}, one arrives at the erroneous conclusion that the final state of the system consists of either all empty or occupied sites (depending on whether $p$ is smaller or larger than 1/2).

It is clear from the evolution rules that a cluster of two or more occupied (or empty) sites remains stable forever. We denote occupied clusters $\bullet \bullet \cdots \bullet$ with a solid rectangular box $\blacksquare$, and empty clusters $\circ \circ \cdots \circ$ with an empty box $\square$.

The initial configuration can be viewed as a collection of stable blocks, separated by alternating sequences of occupied-empty sites. There are only four possibilities:

(a) $\blacksquare \circ \circ \cdots \circ (2n \text{ intervening sites})$

(b) $\square \bullet \bullet \cdots \bullet (2n \text{ intervening sites})$

(c) $\blacksquare \circ \circ \cdots \circ (2n + 1 \text{ intervening sites})$

(d) $\square \bullet \bullet \cdots \bullet (2n + 1 \text{ intervening sites})$

In all of these cases all of the sites in the alternating sequences flip state at each time step. On each step, the two sites at the edges merge with the bounding blocks. Thus, cases (a) and (b) cease to evolve after $n$ steps, and the bounding blocks meet, having each grown by

*Electronic address: benavraham@clarkson.edu
\[ p_s = p + p^4 q(1 + 2pq + 3p^2q^2 + \cdots) - q^4 p(1 + 2pq + 3p^2q^2 + \cdots) = p + \frac{pq(p^3 - q^3)}{(1 - pq)^2}. \]

Thus, unless \( p = 1/2 \), the majority species increases on expense of the minority species (Fig. 1).

We now compute the probability distribution for clusters of \( n \) occupied sites in the steady state. In the initial state, the probability of an \( n \)-cluster is \( P(n) = q^2 p^n \), so the expected length is \( \langle n \rangle_0 = \sum_{n=1}^{\infty} n P(n)/\sum_{n=1}^{\infty} P(n) = 1/q. \)

Fig. 2 lists all the possible scenarios leading to \( n \)-clusters in the steady state. Ultimately, a cluster of occupied sites needs be bounded by empty clusters on the left and right. A series of alternating sites in between does not lead to an occupied cluster (case (c) of Section II) and at the least a two-site cluster (\( \bullet\bullet \)) needs to be present (Fig. 2a). For the final cluster to attain length \( n \), the combined lengths of the alternating sequences abutting the \( \bullet\bullet \) seed should be \( 2(n - 2) \). Because the seed could be initially in any of \( n - 1 \) locations (including right next to the \( \square \) blocks), the total contribution of this case is

\[ P_a(n) = q^4 p^2(n - 1)(pq)^{n-2}, \quad n \geq 2. \]

The initial seed could be three sites long (Fig. 2b), leading to a contribution

\[ P_b(n) = q^4 p^3(n - 2)(pq)^{n-3}, \quad n \geq 3. \]

All other cases are exemplified by Fig. 2c. The shaded block near the center denotes an arbitrary sequence of sites with the property that it contains no two consecutive empty sites (\( \circ \)). All of the sites in such a sequence would end up being occupied in the steady state. Denoting the probability of an \( m \)-sequence of this type by \( \psi_m \), we can express the contribution of this last case as

\[ P_c(n) = q^4 p^4 \sum_{k=0}^{n-4} (k + 1)(pq)^k \psi_{n-4-k}, \quad n \geq 4. \]

To compute \( \psi_n \), denote by \( \xi_n \) the probability of an \( n \)-sequence that contains no \( \circ \)'s and ends with \( \bullet \), and let

\[ \xi_n = \frac{\psi_n}{\psi_{n-1}}. \]
ηₙ denote similar sequences, but ending with ☼. The two quantities satisfy the recursion equations:

\[ \xi_{n+1} = (\xi_n + \eta_n)p; \quad \eta_{n+1} = \xi_n q. \]

Using \( \psi_n = \xi_n + \eta_n \), this can be recast into

\[ \psi_{n+1} = p\psi_n + pq\psi_{n-1}. \tag{4} \]

The solution is,

\[ \psi_n = c_+ r_+^n + c_- r_-^n; \quad r_\pm = \frac{p}{2} \pm \frac{\sqrt{p^2 + 4pq}}{2}, \tag{5} \]

where \( c_\pm \) are determined from the boundary conditions, \( \psi_0 = \psi_1 = 1 \).

Although it is now straightforward to compute \( P(n) = P_a(n) + P_b(n) + P_c(n) \), the resulting expression is cumbersome and not particularly instructive. Instead, we observe that, for large \( n \), \( P(n) \sim r_+^n \). Since \( r_+ > p \) (Fig. 3), the probability for large clusters in the steady state is exponentially larger than in the initial state. For example, for small \( p \), \( r_+ \sim \sqrt{p} \), and \( P(n) \sim p^{n/2} \), compared to \( \sim p^n \) of the initial state.

Despite the cumbersome form of \( P(n) \), the average cluster size in the steady state yields a surprisingly simple expression:

\[ \langle n_\bullet \rangle_s = \frac{\sum nP(n)}{\sum P(n)} = \frac{2-p}{q^2} = (2-p)\langle n_\bullet \rangle_0^2, \tag{6} \]

where for the last equality we are using \( \langle n_\bullet \rangle_0 = 1/q \), for the sake of comparison with the initial state.

As a simple test of our results one can compute \( p_s = \langle n_\bullet \rangle / (\langle n_\bullet \rangle + \langle n_e \rangle) \), where the average length of clusters of empty sites, \( \langle n_e \rangle = (2-q)/p^2 \), is obtained from \( \langle n_\bullet \rangle \) by exchanging \( p \leftrightarrow q \). It is easy to confirm that this agrees with \( p_s \) of Eq. (3). Also, \( 1/(\langle n_\bullet \rangle + \langle n_e \rangle) = \kappa_s \) of Eq. (2), suggesting that there is no correlation between the lengths of adjacent occupied and empty clusters. This seems remarkable, when contrasted with the correlations observed in \( P(n) \) for large \( n \).

IV. DYNAMICS

To analyze the transient behavior of the one-dimensional NCO model, consider the probability \( \pi_t \) that an initially occupied site flips exactly \( t \) times before setting down for good. \( \pi_0 = 2p^2 - p^3 \) is simply the probability that the initially occupied site is stable, i.e., it is the central site in one of the configurations: \( \bullet \bullet \bullet \bullet \circ \bullet \bullet \bullet \circ \circ \).

To \( \pi_t \) contribute the \( \bullet \circ \circ \)’s two sites away from the blocks in cases (a), (b), and (c) of Section II, resulting in

\[ \pi_1 = 2p^2q^2 \frac{pq}{1-pq} + q^4 \frac{1+pq}{1-pq}. \]

To \( \pi_2 \) contribute the \( \bullet \circ \circ \)’s two sites away from the blocks in cases (a), (b) and (d), etc. The general result is

\[ \pi_t = 2p^2q^2 \frac{(pq)^t}{1-pq} + \omega (pq)^{t-1} \frac{1+pq}{1-pq}, \tag{7} \]

where \( \omega = p^t q \) or \( q^4 p \) for even and odd \( n \), respectively. The analogous probabilities, \( \sigma_t \), for a \( \circ \circ \) to flip exactly \( t \) times before stopping are obtained, as usual, by interchanging \( p \leftrightarrow q \) in \( \pi_t \).

Armed with \( \pi_t \) and \( \sigma_t \) one can compute various quantities of interest. For example, the steady-state density is

\[ p_s = \sum_{t=0}^{\infty} (\pi_{2t} + \sigma_{2t+1}), \]

and it is easy to confirm the agreement of this formula with (3). More importantly, the probability that a site, of any kind, is still active at time \( t \) (persistence), is

\[ S_t = \sum_{t=0}^{\infty} (\pi_t + \sigma_t) \sim (pq)^t. \tag{8} \]

The rapid exponential decay of \( S_t \) is typical of other dynamical quantities. In practical terms, the system settles almost instantly to the steady state. An example of this effect can be seen in Fig. 4 where the density of occupied sites after merely one step, \( p_1 \), is compared to the density \( p_s \) of the steady state. An exception is the probability \( P_t(n) \) for finding \( n \)-clusters of occupied sites after \( t \) steps. For small \( p \) and (large \( n \)), it converges slowly to the steady state, as \( P_t(n) \sim p^{\alpha t n} \), with \( \alpha_t = (t+1)/(2t+1) \).

V. NCO ON THE BETHE LATTICE

We now consider the NCO model on the Bethe lattice with coordination number \( z \geq 3 \) (the line can actually
be viewed as a Bethe lattice with $z = 2$). The Bethe lattice with $z \geq 3$ is far richer than the line, in that it sustains phase transitions: being infinite-dimensional, its phase transitions are mean-field in character, as expected above the critical dimension. For percolation, for example, a phase transition occurs at $p = p_c = 1/(z-1)$. For $p > p_c$ there exist an infinite number of infinitely large connected clusters of occupied sites, which are characterized by mean-field critical exponents. This is known as the critical phase. In regular lattices there is no critical phase, and instead there is only one infinite cluster at $p > p_c$, known as the percolative phase [3].

For $z = 3$ the neighborhood of each node consists of 4 sites (including the site itself) and according to the NCO rules a site retains its own state in the event of a tie. It follows that, just as for the line, a two-site cluster is forever stable. At $p > 1/2$ the initial configuration possesses infinitely many infinite percolation clusters. Those clusters will remain stable indefinitely, in the NCO model, perhaps accreting even more of the neighboring sites as the updates take place. Indeed, the threshold $p_c$ for the emergence of infinite clusters, in the NCO model, is actually smaller than $1/2$ (of regular percolation).

We consider a “root” node at $\ell = 0$ and define layer $\ell$ as the set of nodes $\ell$ links away from the root. Let $N_\ell$ denote the number of paths, from the root to layer $\ell$, that never encounter an initially stable empty site, that is, none of the empty sites on a path have an empty neighbor (either on, or branching away from the path). All of the nodes on the $N_\ell$ paths end up occupied in the steady state. Following a similar reasoning to the one we applied for $\psi_n$ on the line, we find

$$N_{\ell+1} = 2pN_\ell + 4p^2 q N_{\ell-1},$$

leading to $N_\ell \sim r^\ell$, with $r = p(1 + \sqrt{1 + 4q})$. The critical point for the emergence of infinite clusters in the NCO occurs therefore for $p_c \approx 0.344446$ — the root of $r = 1$.

To sum up, the NCO model on the $z = 3$ Bethe lattice is very much like percolation in that there is a critical phase of infinitely many infinite clusters at $p > p_c$, and only finite clusters at $p < p_c$. That there is no transition to a percolative phase is clear from the fact that stable oo-clusters are seeded, initially, for all $p$ (other than at the extremum, $p = 1$), preventing the coalescence of all the infinite clusters into a single one.

The situation is even more interesting for $z = 4$. In this case, the neighborhood consists of 5 sites and a minimum of 2 occupied neighbors are required to stabilize a •-site. It is easy to see that under this condition the $z = 4$ Bethe lattice does not support finite stable clusters. However, the infinite percolation clusters are stable also in the NCO model, so it follows that the existence of infinitely many infinite clusters of occupied sites is guaranteed for $p > 1/(z-1) = 1/3$, and may occur somewhat sooner, at $p = p_{c1} \leq 1/3$. At $p < p_{c1}$, infinite clusters fail to form and the steady state is uniformly empty, since finite occupied clusters are unstable and vanish as the NCO updates evolve. The lattice becomes uniformly occupied, at the steady state, for $p > p_{c2} = 1 - p_{c1}$, because of the symmetry between empty and occupied sites under $p \leftrightarrow q$. In other words, the NCO model has now three phases: no infinite clusters, for $p < p_{c1}$; infinitely many infinite clusters, for $p_{c1} < p < p_{c2}$; and a single infinite cluster (consisting of the whole lattice), for $p > p_{c2}$. Unlike regular percolation, there are no finite clusters in the non-critical phases. The situation is similar for $z > 4$.

VI. DISCUSSION

In conclusion, we have presented an exact solution of the NCO model on the line. This analysis is particularly interesting in view of the suspected connection between the NCO model and TIP [1]. It should be noted that while invasion percolation on the line is trivially defined and solved, it is not at all clear how to implement the trapping condition — that is, superficially, there seems to be no difference between invasion percolation and TIP on the line, and neither displays the richness of results found for the NCO model in this paper.

The situation is even more interesting for Bethe lattices. Just as in one dimension, there is no obvious way to distinguish between invasion percolation and TIP. For $z = 3$, the two-phase diagram of the NCO model is the same as that of regular percolation (for any $z$). The three phases found for the NCO model on the Bethe lattice with $z \geq 4$ can be found in regular percolation, but only on hyperbolic lattices and other nonamenable one-ended graphs [5]. Solving the NCO model on Bethe lattices is an appealing open problem. It remains ultimately unclear, however, how to connect the rich behavior of the NCO model on the line and on Bethe lattices to TIP.

Acknowledgments

I thank Erik Boltt, Chris Jizheng, and Wen Luosheng for many useful discussions and for encouraging this line of inquiry.
