Photosynthetic Production of Molecular Oxygen by Water Oxidation

Lars Olof Björn

Department of Biology, University of Lund, SE-223 62 Lund, Sweden; lars_olof.bjorn@biol.lu.se

Abstract: This review deals with the production of oxygen by photo-oxidation of water, which is a topic fitting a journal devoted to oxygen. Most of the present biosphere, including mankind, depends on oxygen. Elucidating the mechanism is of importance for solving the present energy crisis. Photosynthesis evolved in bacteria, first in a form that did not produce oxygen. The oxygen-producing version arose with the advent of cyanobacteria about three billion years ago. The production of oxygen by photo-oxidation of water requires the co-operative action of four photons. These are harvested from daylight by chlorophyll and other pigments (e.g., phycobiliproteins) and are channeled to photosystem II and photosystem I. The oxygen-evolving complex resides in photosystem II, surrounded by protein subunits, and contains one ion of calcium, four ions of manganese, and a number of oxygen atoms. For each quantum of energy it receives from absorbed light, it proceeds one step through a cycle of states known as the Kok–Joliot cycle. For each turn of the cycle, one molecule of oxygen (O₂) is produced.

Keywords: oxygen; oxygen-evolving complex; photosynthesis; photosystem II

1. Introduction

Life arose on our planet in a reducing environment. The first kind of photosynthesis probably did not involve the evolution of molecular oxygen, but this complicated process evolved at least 3 billion years ago, as evidenced in a number of ways. Analysis of genomes indicates that cyanobacteria had already evolved at that time [1]. The lack of variability in the ratio of uranium isotopes in pre-3.0 Ga iron formation samples suggests minimal presence of dissolved U(VI) in rivers and seawater (indicating anoxic conditions); however, 2.95 billion years ago, this started to change [2]. By comparing the abundances of iron and other metals in sediments of ancient shallow oceans, Satkoski et al. [3] came to the conclusion that they contained oxygen 3.2 billion years ago.

Why do I say that evolution of molecular oxygen is a complicated process? Oxidation of water to O₂ is not only energy-demanding; it also requires the co-operative action of four photons, arriving at random times, to remove four electrons from two water molecules. How this can happen and how it evolved is not clear. Let me first describe what we think we know about the mechanism and then speculate about how it has come to be.

In plants and algae, photosynthesis takes place in cell parts called chloroplasts, which are a few micrometers in size. They were derived from cyanobacteria more than a billion years ago, and the photosynthetic structures in chloroplasts and cyanobacteria are quite similar. They contain chlorophylls and carotenoids, as well as phycobiliproteins in cyanobacteria, which absorb the light that drives oxidation of water to molecular oxygen coupled with a reduction of carbon dioxide to carbohydrate. The light energy is absorbed by two large protein complexes with associated pigment molecules, called photosystem I and photosystem II (Figure 1). They reside in so-called thylakoid membranes, which are closed structures (thylakoids) with different inside and an outside structures. Here, we shall concentrate on photosystem II (PSII), which is the that which carries out the oxidation of water to oxygen molecules.
The sequence of flashes resulted in an approach toward a constant oxygen yield per flash. The photosystem II complex, which is one of the proteins in the thylakoid membranes in place is called the Mn

photosynthesis, including assimilation of one CO

positive charge until enough is available for oxidation of the water molecules. This is independently, by Pierre Joliot et al. [5] and Bessel Kok et al. [6]. When they exposed Chlorella algae or spinach chloroplasts that had been in darkness for some time to repeated very short and intense light flashes, they observed no oxygen after a single flash, a maximum of oxygen (O

short and intense light flashes, they observed no oxygen after a single flash, a maximum of production after the third flash, and thereafter on every fourth flash (Figure 2). The sequence of flashes resulted in approach toward a constant oxygen yield per flash. The gradual levelling out is due to the fact that even these very short flashes often result in more than one step forward (in some cases, there is no hit at all) in what has come to be known as the “Kok cycle” or the “Joliot–Kok clock” (Figures 3B and 6). Structures of the intermediates in this “clock” have been described by Umena et al. [7], Suga et al. [8], and Kern et al. [9]. All details in this cycle are not yet clarified, and various possible versions are discussed by Li et al. in [10].

Because photons arrive at random times and four photons are needed for the production of one oxygen molecule, there must be some mechanism for storing energy and positive charge until enough is available for oxidation of the water molecules. This is achieved by the four manganese atoms of the Kok cycle (Figure 3B), in steps proceeding from Mn

IV

4+ to Mn

IV

8+. A minimum of four more photons are needed for complete photosynthesis, including assimilation of one CO2 molecule.

The molecular structure in which the oxidation of water to molecular oxygen takes place is called the Mn4CaO5 cluster (Figure 3A). The structure was first reported by Shen’s group, Umena et al. [6] and Suga et al. [7].

Figure 4 shows a schematically of how the Mn4CaO5 cluster forms part of the large photosystem II complex, which is one of the proteins in the thylakoid membranes in cyanobacteria and in the chloroplasts of algae and other plants.
In experiments with the extremophilic red alga *Cyanidoschyzon merolae* and comparing with results from spinach, Pham et al. [12] explained, in detail, patterns such as that shown in Figure 2 and arrived at the conclusion that the S2-to-S3 transition is the least efficient step during the oxidation of water to O2. It is also the step that has been most thoroughly investigated and divided into substeps. Thus, Klauss et al. [13] found that the proton transfer in this step precedes the electron transfer. They observed an exceptionally high activation energy of 540 ± 30 meV for the proton transfer. However, Amin et al. [14] concluded that even prior to the proton transfer step, oxidation of one of the manganese

![Figure 2](image2.png)

**Figure 2.** Yield of molecular oxygen from *Chlorella* cells as a function of flash number. The first flash does not result in any oxygen; the first maximum comes on the third flash. Thereafter, maxima occur on every fourth flash, and the oscillation gradually decreases towards a flat line (steady state). Redrawn and modified from Joliot et al. [4]. Kok et al. [5] obtained very results with spinach chloroplasts. (See also Joliot & Kok [11]).

![Figure 3](image3.png)

**Figure 3.** (A) The oxygen-evolving complex (OEC). The four manganese ions are colored violet, the six oxygen atoms are indicated in red, and the calcium atom is indicated in yellow. W1 to W4 are water molecules. (B) The Kok cycle (also called the Kok-Joliot cycle). S0 to S4 are the OECs in various states, without or with a positive charge, with oxidation states of the manganese indicated. Yellow circles labelled hv indicate quanta from light. When S2+ changes to S3+, a water molecule is taken up, and an electron and a proton are released. When S3+ changes to S3, a water molecule is taken up, and a proton and an oxygen molecule are released. In darkness, the equilibrium state is mainly S1. Graphics by D. Shevela (SciGrafik, Sweden).
ions and a change of spin takes place, resulting in a change in the EPR signal from \( g = 2 \) to \( g = 4.1 \). The structural changes taking place during the \( S_2 \)-to-\( S_3 \) transition were studied by Ibrahim et al. [15].

**Figure 4.** Photosystem II: The water-splitting enzyme of photosynthesis. D1 and D2 are the central polypeptides in a very large complex in the thylakoid membranes of cyanobacteria and chloroplasts. Electrons from water are transferred via the “Mn\(_4\)CaO\(_5\)” cluster, the tyrosine Y\(_z\) in D1, P680 (an ensemble of chlorophyll \( a \) molecules), Pheo (pheophytin), and Q\(_A\) (a molecule of plastoquinone attached to D2) to Q\(_B\), another molecule of plastoquinone, which, after receiving two electrons, dissolves in the membrane and will be used as reductant in further reactions (as PQH\(_2\)). Reproduced with permission of SciGrafik (Sweden) and Agrisera (Sweden).

It is easy to forget that chlorine is one of the essential elements for plants, as deficiency seldom occurs under natural or agricultural conditions. However, as Mandal et al. [16] showed, chloride ions are necessary for the transition from state \( S_2 \) to state \( S_3 \) of the oxygen-evolving complex (Figure 5).

Using photoacoustics and a method called “photothermal beam deflection”, which, with high time resolution, monitors volume changes in the system, Klauss et al. [17,18] were able to separate and time several steps of electron and proton transfer in the Kok cycle for particles from spinach from \( S_2^+ \) to \( S_0 \). State \( S_4 \), originally proposed by Kok, has never been directly identified.
Figure 5. When a chloride ion (Cl\textsuperscript{–}) is present in the OEC, the transfer of an electron from water, via manganese ion 1 (Mn1) (and change between S\textsubscript{2} and S\textsubscript{3} states of the OEC) and tyrosine Z, to the plastoquinone B (Q\textsubscript{B}) on the D1 polypeptide goes downhill, i.e., toward higher redox potential (E\textsubscript{m}). In the absence of Cl\textsuperscript{–}, the redox potential of Mn1 is increased beyond that of tyrosine Z, and Mn1 cannot be oxidized; the electron transfer to tyrosine Z is blocked. From Mandal et al. \[16\]. Reproduced with permission from the authors. A detailed energy diagram of the S\textsubscript{0}–S\textsubscript{1}–S\textsubscript{2} transitions in the native state was published by Siegbahn [19].

3. The Role of Manganese

As shown in Figure 3B, the molecular oxygen (two red spheres) is released during the transition from the hypothetical (never observed) state S\textsubscript{4}\textsuperscript{+} to S\textsubscript{0}. Figure 6 shows the changes in the OEC during this transition. In the S\textsubscript{4} state, oxygen atoms 5 and 6 (labelled O5 and O6) form part of the distorted OEC cube. In the next structure, with lower internal energy, they are released, and the “cube” is opened. One of the oxygen atoms is then replaced by oxygen, with a hydrogen atom attached, from the water molecule labelled W3 in Figure 3 to close the structure again. The transition from S\textsubscript{4} to S\textsubscript{0} can take place without energy input from light because the internal energy is lower for the S\textsubscript{0} structure than that for the S\textsubscript{4} structure. It is important to note that Figure 6 is tentative, showing one of several possible mechanisms; many other possible versions of the cycle have been published [13,20–24]. It is too early to draw a final version of this cycle.
4. The Role of Calcium

The calcium ion is essential for the function of the Mn4CaO5 cluster. It can be removed by various methods and added back with restoration of function, and function can also be restored to some extent by strontium (Sr⁴⁺) [28] (see also Gates et al. (2016) [29]). Based
on EPR signals, vanadyl ions (VO$_2^+$) have an effect similar to that of strontium ions [30]. All the transitions of the Kok–Joliot cycle, except the S$_0$-to-S$_1$ transition, are inhibited in the absence of a calcium ion [31]. Removal of the calcium ion reveals that it is not essential for the OEC structure [32,33], although some changes in the hydrogen bonding of water molecules take place [34]. So, what is the function of Ca$^{2+}$? Nagashima et al. [35] arrived at the conclusion that Ca$^{2+}$ maintain the hydrogen bond network near the Ca$^{2+}$ site and provides of an electron transfer pathway to the manganese cluster. Yao et al. [36] have shown, in model experiments with synthetic clusters mimicking Mn$_4$CaO$_{4}$, that gadolinium and yttrium provide almost the same structure and electrical properties as calcium. Tsui and Agapie [37] demonstrated, with inorganic manganese-oxido-cubane complexes, how the redox potential is modified by various redox-inactive metals and that strontium and calcium have very similar effects.

An interesting observation was made by Bang et al. [38]. They found that Ca$^{2+}$ ions, as well as Sr$^{2+}$ ions, could cause the release of O$_2$ from non-haem iron(III)–peroxo complexes in the presence of an electron acceptor (e.g., 1-benzyl-1,4-dihydronicotinamide dimer). The authors attributed this effect to the ion acting as a Lewis acid, i.e., accepting an electron pair. It is likely that Ca$^{2+}$ in the OEC functions in the same way. Other examples of Ca$^{2+}$ acting as a Lewis acid, facilitating various reactions, were reviewed by Begouin and Niggemann [39] and Hill et al. [40].

5. The Role of Bicarbonate in PSII Function

Boyle [41] noted an “apparent necessity of minute quantities of CO$_2$ to bring about oxygen evolution” in a Hill reaction with p-benzoquinone as the electron acceptor. Warburg and Krippahl [42] confirmed the effect. A number of other researchers later repeated and extended these experiments, showing that the effect is due to bicarbonate ions rather than carbon dioxide and that it is quite separate from the role of carbon dioxide as a substrate for carbon assimilation. Wydrzynski and Govindjee [43] observed an effect of bicarbonate on the fluorescence from PSII. They concluded that “the bicarbonate affects the primary reactions in photosynthesis” and that it “is specific for Photosystem II”. Brinkert et al. [44] found that the removal of bicarbonate shifts the midpoint redox potential of the couple Q$_A$/Q$_A^-$ from $\sim$−145 mV to −70 mV. Based on EPR measurements, Vermaas and Rutherford [45] concluded that the bicarbonate influences the conformation of the Q$_A^-$Fe$^{2+}$ complex. Shevela et al. [46] found that when spinach thylakoids are depleted of carbon dioxide and bicarbonate, the miss probability in the Kok cycle is higher than under ambient conditions and that the addition of 5 mM bicarbonate to thylakoids depleted of inorganic carbon largely restores the original miss parameter. Shevela et al. [4] found that bicarbonate affects not only the reducing side but also the oxidizing side of PSII (Figure 6). It is unlikely that bicarbonate is tightly bound to the oxygen-evolving complex [47–49].

One bicarbonate ion per photosystem II becomes firmly bound, i.e., the one bound to the iron ion between Q$_A$ and Q$_B$, whereas other bicarbonate ions help to shuffle protons around [50,51].

An interesting observation is that the purple anoxygenic bacterium *Rhodovulum iodosum* is able to oxidize Mn$^{2+}$ to Mn$^{3+}$ in the presence of bicarbonate, although not in its absence [52]. *Rhodovulum iodosum* has a type-2 photosystem. The mechanism by which carbonate and bicarbonate facilitate water oxidation in artificial systems was reviewed by Mizrahi and Meyerstein [53]. Bicarbonate has been directly shown to shift the midpoint redox potential of the Mn$^{2+}$/Mn$^{3+}$ couple in modified reaction centers of *Rhodobacter sphaeroides* mutants from 625 mV to 535 mV [54]. With pea chloroplasts, Kozlov et al. [55] identified two Mn-bicarbonate complexes with three bicarbonate ions per complex and midpoint redox potentials of 610 mV and 520 mV, respectively.

6. Assembly of the Oxygen-Evolving Complex

For an overview of photosystem II assembly, see [56]. Here, we shall focus on the OEC. Manganese is imported into the OEC protein as Mn$^{2+}$, and oxidation to Mn$^{3+}$ is
achieved by $Y_z^\ast$ generated by light-induced charge separation in the same way as in photosynthesis [57,58]). Only one Mn ion can be imported until structural changes in the protein have taken place. A small soluble protein in the lumen, Pbs27, aids the process by transiently binding to PSII (see [58] for details). The quantum yield of the process is low—much lower than the quantum yield for photosynthesis [59]—although to some degree, it is increased by the presence of Ca$^{2+}$ [60–62]. Chloride, in association with the OEC, facilitates the oxidation of Mn$^{2+}$ [63], with two chloride ions in PSII near the OEC [6]. The low quantum yield was explained by Sato et al. [64], with back reactions proceeding faster than forward reactions (Figure 7). The calcium ion protects the system from photoinactivation [62].

![Figure 7. The initial stages of photoassembly of the OEC; redrawn and modified from Sato et al. [64]. The first light reaction is counteracted by a dark reaction that is much faster than incorporation of calcium ions, a second manganese ion, and rearrangement of the protein scaffolding. This leads to an overall low quantum yield. Complete photoactivation of the OEC requires a secondary photon absorption [65] (Figure 7).](image)

7. Evolution of Oxygen Evolution

Oxygenic photosynthesis is a complicated process. How could it arise so early in the evolution of life on Earth? Nothing is known with certainty, but various explanations have been proposed. Sauer and Yachandra [66] point to structural similarities between the OEC and certain minerals. Dismukes et al. [67] suggest that the first kind of oxygenic photosynthesis to evolve produced molecular oxygen from bicarbonate ions rather than from water. One theory is that the evolution of water-oxidizing photosynthesis was preceded by a form in which mineral manganese (Mn$^{2+}$) was oxidized. Chernev et al. [68] created a model of this system by removing the Mn$_4$CaO$_5$ cluster from purified spinach PSII, which also resulted in the loss of three extrinsic proteins (PsbQ, PsbP, and PsbO). When Mn$^{2+}$ ions were supplied at a low concentration, only a minimal electron transport to an added artificial electron acceptor was observed. The results with a higher Mn$^{2+}$ concentration (240 µM) are interpreted as rapid oxidation of manganese and formation of Mn(III/IV) oxide particles, similar to the mineral birnessite (confirmed by X-ray spectroscopy). Chernev et al. [68]
suggest that “in the evolution of PSII, there may have been a transition from extended Mn-oxide nanoparticles towards the Mn₄CaO₅₅ cluster of today’s PSII”. They further point out that “a Mn oxide denoted as ranciéite is isostructural to birnessite and contains Mn and Ca ions at approximately the same 4:1 stoichiometry as present in the Mn₄CaO₅ cluster of PSII”.
