Laboratory experiments have confirmed that the radiolytic decay rate of astrochemical ice analogues is dependent upon the solid phase of the target ice, with some crystalline molecular ices being more radio-resistant than their amorphous counterparts. The degree of radio-resistance exhibited by crystalline ice phases is dependent upon the nature, strength, and extent of the intermolecular interactions that characterise their solid structure. For example, it has been shown that crystalline CH$_3$OH decays at a significantly slower rate when irradiated by 2 keV electrons at 20 K than does the amorphous phase due to the stabilising effect imparted by the presence of an extensive array of strong hydrogen bonds. These results have important consequences for the astrochemistry of interstellar and Solar System ices and the formation of sulphur allotropes and residues in these settings.
Introduction

It has been established for some time now that the laboratory irradiation of astrochemical ice analogues using energetic charged particles (i.e., ions and electrons) or ultraviolet photons may lead to the production of prebiotic molecules relevant to biology, such as amino acids or nucleobases (e.g., Muñoz-Caro et al., 2002; Hudson et al., 2008; Nuevo et al., 2012). Motivated by a desire to further understand the non-equilibrium chemistry leading to the formation of these so-called ‘seeds of life’, many studies have sought to determine and quantify the influence of various physical parameters on the outcome of such reactions. Perhaps the best studied of these is ice temperature, with previous works having demonstrated the key influence of this parameter on the abundance of product molecules formed after irradiation (e.g., Sivaraman et al., 2007; Mifsud et al., 2022a).

Our recent work has also demonstrated that the solid phase of an irradiated ice plays a crucial role in determining the outcome of astrochemical reactions mediated by ionising radiation. Through a series of comparative electron irradiations, we have demonstrated that the radiolytic decay rate of an astrochemical ice is dependent upon the nature, strength, and extent of the intermolecular interactions that characterise its solid phase (Mifsud et al., 2022b; Mifsud et al., 2022c). For instance, the decay rate of α-crystalline CH$_3$OH was found to be significantly less rapid than that of the amorphous phase. This was attributed to the existence of an extensive network of strong hydrogen bonds that exists in the α-crystalline phase. This network requires an additional energy input from the projectile electrons to be overcome, thus leaving less energy overall to drive radiolytic chemistry. Conversely, the amorphous CH$_3$OH ice is characterised only by localised clusters of hydrogen bonded molecules. Such a structure does not benefit from the same stabilising effect supplied by the network of hydrogen bonds in the α-crystalline phase, particularly as hydrogen bonding in CH$_3$OH is known to be a cooperative phenomenon in which the presence of one hydrogen bond in the network strengthens successive hydrogen bonds through electrostatic effects (Kleeberg and Luck 1989; Sum and Sandler 2000).

In the case of N$_2$O ice, the decay rate of the amorphous phase was noted to be only moderately more rapid than that of the crystalline phase (Mifsud et al., 2022b). The dominant intermolecular forces of attraction in solid N$_2$O are expected to be dipole-dipole interactions. Although the orientation of these dipoles in the crystalline phase is anticipated to confer some degree of resistance against radiolytic decay compared to the amorphous phase, this is considerably less than that induced by the hydrogen bonding network in α-crystalline CH$_3$OH. This therefore explains the more similar radiolytic decay rates of amorphous and crystalline N$_2$O. Such results carry important implications for the radiation processing of astrochemical ices, as they suggest that the irradiation of amorphous ices is more chemically productive than that of crystalline ones; particularly in the case of those ices which are able to form strong and extensive intermolecular bonds when crystalline. Extending this idea further, it is entirely possible that those astrophysical environments in which space radiation-induced amorphisation processes dominate over thermally-induced crystallisation may be characterised by a more productive radiolysis. This idea is not unreasonable, particularly in light of the discovery of several complex organic molecules in pre-stellar cores (e.g., McGuire et al., 2020; Burkhardt et al., 2021).

In this present study, we have expounded upon our previous work by performing comparative electron irradiations of the crystalline and amorphous phases of pure H$_2$S and SO$_2$ astrochemical ice analogues, thus simulating the processing such ices undergo during their interaction with galactic cosmic rays, stellar winds, or magnetospheric plasmas as a result of the production of large quantities of secondary electrons (Mason et al., 2014; Boyer et al., 2016). Solid H$_2$S is known to exhibit a number of stable crystalline phases under low temperature and ambient pressure conditions (Fathe et al., 2006), but it is the crystalline phase III (hereafter simply referred to as the crystalline H$_2$S phase) which is of importance under conditions relevant to astrochemistry. This phase is orthorhombic, having eight molecules per unit cell and adopting the Pbcm space group. SO$_2$ may also exist as an orthorhombic crystalline solid under astrochemical conditions, but in this case the Ab2 space group is adopted and there are only two molecules per unit cell (Schröver-Mazzuoli et al., 2003).

Although sulphur is one of the most abundant elements in the cosmos and is of importance in both biochemical and geochemical contexts, much remains unknown regarding its chemistry in interstellar and outer Solar System settings (Mifsud et al., 2021a). It is thought, for instance, that H$_2$S ice processing by galactic cosmic rays or ultraviolet photons accounts for the apparent depletion of sulphur (relative to its total cosmic abundance) in dense interstellar clouds by producing large quantities of atomic sulphur or molecular sulphur chains and rings which are difficult to detect using current observation techniques (Jiménez-Escobar and Muñoz-Caro 2011; Jiménez-Escobar et al., 2014). H$_2$S itself has not yet been definitively detected in interstellar icy grain mantles (Boogert et al., 2015). Conversely, SO$_2$ ice has been detected within both the dense interstellar medium as well as on the surfaces of outer Solar System bodies such as the Galilean moons.
of Jupiter (Boogert et al., 1997; Carlson et al., 1999). However, the exact chemical mechanisms leading to its formation in these settings remain widely debated (Mifsud et al., 2021a).

The purpose of this study is thus two-fold: (i) to determine whether the phase of irradiated sulphur-bearing molecular ices influences the radiation-induced rate of decay as was previously demonstrated for non-sulphur-bearing ices; and (ii) to contribute further to our (comparatively poor) understanding of the extra-terrestrial chemistry of sulphur. To achieve these goals, the amorphous and crystalline phases of pure H2S and SO2 ices were respectively irradiated with 2 and 1.5 keV electrons, and the resultant physico-chemical changes were followed in situ using Fourier-transform mid-infrared (FT-IR) transmission absorption spectroscopy.

Experimental methodology

The irradiation experiments were performed using the Ice Chamber for Astrophysics-Astrochemistry (ICA); a custom-built experimental apparatus located at the Institute for Nuclear Research (Atomki) in Debrecen, Hungary. This apparatus (Figure 1) has been described in detail in previous publications (Mifsud et al., 2021b; Herczku et al., 2021), and so only a brief description of the most salient details will be provided here. The ICA is a UHV-compatible chamber with a nominal base pressure of a few 10−9 mbar which is achieved by the combined action of a dry rough vacuum pump and a turbomolecular pump. Within the centre of the chamber is a gold-coated oxygen-free copper sample holder which supports up to four ZnSe deposition substrates, onto which astrochemical ice analogues may be prepared. The temperature of the sample holder and the substrates may be cooled to 20 K using a closed-cycle helium cryostat, although an operational temperature range of 20–300 K is available.

The preparation of H2S and SO2 astrochemical ice analogue phases was achieved via background deposition by allowing the relevant gas into a pre-mixing line before dosing it into the main chamber at a pressure of a few 10−8 mbar. Amorphous ice phases were prepared by deposition at 20 K, while crystalline H2S and SO2 ices were prepared by deposition at 60 and 90 K, respectively, before being cooled to 20 K. Once deposited, FT-IR spectra (spectral range = 4,000–650 cm−1; spectral resolution = 1 cm−1) of the ices were acquired, from which quantitative measurements of their molecular column densities N (molecules cm−2) and thicknesses d (μm) could be performed by measuring the peak area P (cm−1) of a characteristic absorption band (Eq. 1):

$$d = 10,000 \times \frac{NZ}{N_A \rho} = 10,000 \times \ln(10) \times \frac{PZ}{A_N \rho}$$

where Z is the molar mass (g mol−1) of the molecular ice, N_A is the Avogadro constant (6.02×1023 molecules mol−1), ρ is the density of the ice (g cm−3), and A_N is the band strength constant of the characteristic absorption band whose area is being measured (cm molecule−1). Information on the molecular column densities and thicknesses of the ices investigated in this study, as well as the physical parameters used to calculate these values, is given in Tables 1 and 2.

The deposited pure H2S and SO2 astrochemical ices were respectively irradiated using 2 and 1.5 keV electron beams (average flux = 4×1015 electrons cm−2 s−1) to a total fluence of about 8.3×1016 electrons cm−2, with projectile electrons impacting the target ices at an angle of 36° to the normal. Prior to commencing the irradiations, the beam current, spot size, and profile homogeneity were determined using the method described by Mifsud et al. (2021b). CASINO simulations (Drouin et al., 2007) of the trajectory of the electrons as they travelled through the solid ices revealed that the maximum penetration depths of the incident electrons into the H2S and SO2 ices were 155 and 70 nm, respectively. FT-IR spectra were collected at several intervals throughout the irradiation process so as to monitor the radiation chemistry occurring. All irradiations were carried out at 20 K so as to preclude any temperature-dependent effects on the mobility of radiolytically derived radicals. Moreover, the irradiation of each ice phase was performed three times so as to ensure good repeatability of the experiment.

Results and discussion

The FT-IR spectra of the pure H2S and SO2 ice phases investigated in this study, both before and after irradiation by electrons at different fluences, are depicted in Figure 2. In the
amorphous phase, H2S presents a very broad absorption band which peaks at 2,550 cm$^{-1}$ attributable to both the symmetric ($\nu_1$) and asymmetric ($\nu_3$) stretching modes. In the crystalline phase, this band is better resolved and the individual contributors may be observed. The asymmetric stretching mode is observed to peak at 2,546 cm$^{-1}$, while the symmetric stretching mode is split into two components peaking at 2,534 and 2,522 cm$^{-1}$. Fathe et al. (2006) also observed this splitting and attributed it to the existence of two unique sulphur atoms and three unique S–H bonds in the unit cell.

The amorphous phase of solid SO2 presents two distinct albeit broad absorption asymmetric and symmetric stretching mode bands which respectively peak at 1,320 and 1,148 cm$^{-1}$. In the crystalline phase, these bands are observed to be better resolved, with three and two individual structures being observed in the asymmetric and symmetric stretching mode bands, respectively. These structures have been attributed to the various isotopologues of SO2 (Schriver-Mazzuoli et al., 2003): the bands peaking at 1,323, 1,309, 1,303, and the shoulder band at 1,301 cm$^{-1}$ are respectively attributed to the transverse B$_1$(TO) and B$_2$(TO) modes of $^{32}$S$^{16}$O$_2$, and to $^{34}$S$^{16}$O$_2$ and $^{32}$S$^{16}$O$_{18}$O; while those peaking at 1,143 and 1,140 cm$^{-1}$ are respectively attributed to the transverse A$_1$(TO) mode of $^{32}$S$^{16}$O$_2$ and to $^{34}$S$^{16}$O$_2$. It is interesting to note that, the naturally low abundances of $^{34}$S and $^{18}$O do not result in weaker band intensities for the SO2 isotopologues containing these isotopes due to intermolecular coupling between these isotopologues in the condensed phase (Brooker and Chen 1991; Schriver-Mazzuoli et al., 2003).

The onset of electron irradiation brings about noticeable changes in the appearances of the spectra of the pristine ices. Perhaps the most prominent of these is the significant broadening of the crystalline ice absorption bands, which also lose their resolved individual structures. This is due to radiation-induced amorphisation, which has been well documented in several ice species irradiated by ions, electrons, and ultraviolet photons; including H$_2$O, CH$_3$OH, N$_2$O, and NH$_3$ (e.g., Kouchi and Kuroda 1990; Moore et al., 2007a; Famá et al., 2010; Mifsud et al., 2022b; Mifsud et al., 2022c). It is interesting to note that, even at the end of the irradiation process once a fluence of $>8 \times 10^{16}$ electrons cm$^{-2}$ has been delivered to the crystalline ices, the appearances of their absorption bands are still not identical to those of the deposited amorphous ices. Indeed, small signs of crystallinity (e.g., the presence of shoulder bands or shifted band peak positions) are still observable in the crystalline ices at the end of irradiation. As such, these irradiated ices are likely largely amorphous but with some small degree of remnant structural order.

The irradiation of molecular ices is known to initiate a rich chemistry leading to the formation of new species. Previous studies have established that irradiated H$_2$S ices efficiently...
yield H$_2$S$_2$ as well as higher order polysulphanes (H$_2$S$_n$, where $x > 2$) in addition to allotropic forms of elemental sulphur (Shingledecker et al., 2020; Cazaux et al., 2022). In our experiments, we have observed the formation of H$_2$S$_2$ through the development of its vibrational stretching modes which appear as a broad shoulder band on the lower wavenumber end of the analogous H$_2$S absorption bands at about 2,500 cm$^{-1}$ (Figure 2; Moore et al., 2007b). The chemistry leading to the formation of H$_2$S$_2$ (as well as higher order polysulphanes) is thought to be largely mediated by HS radicals formed via the dissociation of the parent H$_2$S molecules:

$$\text{H}_2\text{S} \rightarrow \text{HS} + \text{H}$$  \hspace{1cm} (2)

$$2\text{HS} \rightarrow \text{H}_2\text{S}_2$$  \hspace{1cm} (3)

It should be noted that HS radicals produced as a result of the radiolytic dissociation of H$_2$S may pick up an electron to form HS$^-$ ions. These HS$^-$ ions may possibly participate in chemistry leading to the formation of other HS radicals via proton abstraction reactions with H$_2$S, after which the resultant HS ion may undergo electron auto-detachment to yield HS. A similar process has recently been demonstrated to occur in H$_2$O ice with respect to radiolytically derived OH radicals and OH$^-$ ions (Kitajima et al., 2021).

The irradiation of the SO$_2$ ice phases was also observed to lead to the formation of new molecules; in particular SO$_3$ for which was observed through its asymmetric stretching absorption band at 1,388 cm$^{-1}$ (Guldan et al., 1995). SO$_3$ formation in irradiated SO$_2$ ices has been studied extensively and is believed to be the result of the dissociation of the latter species to yield free oxygen atoms which may then bond with other SO$_2$ molecules (Moore et al., 2007b). It should be noted, however, that earlier studies by Pilling and Bergantini (2015) and de Souza Bonfim et al. (2017) have demonstrated that electronically excited SO$_2$
may also abstract oxygen atoms from either an adjacent SO$_2$ molecule or from a O$_2$ molecule; the latter having likely been formed as a result of the double ionisation of the SO$_2$ parent molecule followed by electron neutralisation as described recently by Wallner et al. (2022):

\[
\text{SO}_2 \rightarrow \text{SO} + \text{O} \quad (4)
\]

\[
\text{SO}_2 + \text{O} \rightarrow \text{SO}_3 \quad (5)
\]

\[
\text{SO}_2^+ + \text{SO}_2 \text{ (or O}_2\text{) } \rightarrow \text{SO}_3 + \text{SO} \text{ (or O)} \quad (6)
\]

Differences in the parent molecule decay trends and in the abundance of molecular products observed after irradiation were noted between the studied amorphous and crystalline ice phases. Considering first the decay trends of the amorphous and crystalline H$_2$S ices: it was noted that the rate of decay of the crystalline phase was significantly slower than that of the amorphous phase (Figure 3). A similar trend was observed during the comparative electron irradiations of the amorphous and crystalline phases of CH$_3$OH, N$_2$O, and H$_2$O ices (Mifsud et al., 2022b; Mifsud et al., 2022c). This was attributed to the additional energy input required to disrupt the extensive intermolecular forces of attraction that characterise the crystalline solid before radiolytic chemistry as a result of molecular dissociation may proceed. In CH$_3$OH, the α-crystalline phase contains extensive arrays of cooperative and strong hydrogen bonds which stabilise the ice considerably against radiolytic decay compared to the amorphous solid, which is only characterised by localised hydrogen bonds (Kleeberg and Luck 1989; Sum and Sandler 2000; Mifsud et al., 2022b).

H$_2$S is also capable of forming hydrogen bonds between adjacent molecules (Das et al., 2018), although these are significantly weaker than those in alcohols: the hydrogen bond strengths in pure CH$_3$OH and H$_2$S are 6.3 and 1.0 kcal mol$^{-1}$, respectively (Pellegrini et al., 1973; Bhattacherjee et al., 2013). Despite this weaker nature of the hydrogen bond in H$_2$S, it still displays a relative stability of the crystalline phase to radiation-induced decay (compared to the amorphous phase) that is qualitatively similar to that of CH$_3$OH. As such, it is likely that another factor should be invoked to account for the relative radio-resistance of the crystalline phases of these ices; that of lattice energies. The energetic advantage induced by the ordering of the molecular components of the solid ice must also be overcome and thus a proportion of the incident electrons’ kinetic energy must be expended upon overcoming both the lattice energy as well as the more extensive hydrogen bonding network in the crystalline phase, leaving less energy to induce the molecular dissociation that drives radiolytic chemistry.

Such an interpretation is wholly consistent with our previously reported results on the comparative electron irradiations of amorphous and crystalline N$_2$O, which demonstrated only a moderately more rapid decay rate of the former compared to the latter (Mifsud et al., 2022b). In that case, a fraction of the kinetic energy of the incident electrons must be used to overcome both the increased ordering of the molecular dipoles as well as the crystal lattice energy. We also note that $A_\alpha$ differs by a factor-of-two-and-a-half between the amorphous and crystalline H$_2$S phases, with that of the latter being greater. This is not insignificant, and the rapid amorphisation of the crystalline phase as a result of its irradiation may mean that column density...
measurements of this phase may be somewhat underestimated and, as such, the radio-resistance of the crystalline phase may be even greater than that depicted in Figure 3, although this is difficult to quantify.

The radiation-induced decay trends of amorphous and crystalline SO$_2$ (Figure 4), however, are significantly different to those of H$_2$S and the previously studied ices. The decay trend of the crystalline SO$_2$ ice initially exhibits the anticipated profile of a rapid exponential decay. However, once a fluence of about $1.4 \times 10^{16}$ electrons cm$^{-2}$ is exceeded, the normalised column density declines significantly more slowly. Perhaps even more surprising is the fact that the amorphous SO$_2$ normalised column density (with respect to the initial SO$_2$ column density deposited) does not really vary at low electron fluences, having an average normalised column density of 0.97 after a fluence of $8.2 \times 10^{16}$ electrons cm$^{-2}$ had been delivered. For comparison, by the point this fluence had been delivered to the crystalline SO$_2$ ice, its average normalised column density had decreased to 0.83. However, similarly to the case of the crystalline SO$_2$ ice, once a fluence of about $1.4 \times 10^{16}$ electrons cm$^{-2}$ had been delivered, the normalised column density was observed to undergo a slow exponential-like decay. Interestingly, beyond a delivered fluence of $1.4 \times 10^{16}$ electrons cm$^{-2}$, the rate of decay of the amorphous SO$_2$ is greater than that of the crystalline SO$_2$, and indeed the average decay trends cross one another at a fluence of about $5.3 \times 10^{16}$ electrons cm$^{-2}$.

Providing an exact reason for the observed amorphous SO$_2$ decay trends is a challenging task. Measurements of the photo-desorption of SO$_2$ molecules from an amorphous ice induced by soft x-rays allowed de Souza Bonfim et al. (2017) to suggest that, at low fluences, the recombination of fragments produced by the dissociation of SO$_2$ to yield electronically excited SO$_2$ may be a favourable process, thus largely precluding net SO$_2$ dissociation within the ice. It is also possible that the irradiation of the amorphous SO$_2$ ice results in its compaction, which may cause an increase in $A_\nu$ of the measured band (Figure 2).

As a final analytical consideration, we have attempted to establish the sulphur budget of the electron irradiation processes presented in this study. The possible chemical transformations of H$_2$S and SO$_2$ to infrared inactive atomic or allotropic forms of sulphur have already been referred to (Shingledecker et al., 2020; Cazaux et al., 2022), and so it is useful to quantify how much of the initially deposited H$_2$S or SO$_2$ ice ends up in such a form as a result of its irradiation. As depicted in Figure 2, the only major infrared active products of H$_2$S and SO$_2$ irradiation were H$_2$S$_2$ and SO$_3$, respectively. We have quantified the column densities of these product molecules throughout the irradiation processes by measuring the peak areas of their primary absorption bands and making use of Eq. (1) (Figure 5). We note that we have taken $A_\nu$ for the H$_2$S$_2$ absorption band at about 2,500 cm$^{-1}$ to be $2.4 \times 10^{-17}$ cm molecule$^{-1}$ (Cazaux et al., 2022). To the best of our knowledge, $A_\nu$ has not yet been defined for the SO$_3$ absorption band at 1,388 cm$^{-1}$, and so we have followed the example of de Souza Bonfim et al. (2017) who assumed that this band strength is equal to that of the SO$_2$ asymmetric stretching mode which is $1.47 \times 10^{-17}$ cm molecule$^{-1}$ (Garozzo et al., 2008).
As expected, the yield of H$_2$S$_2$ from the irradiated amorphous H$_2$S ice is greater than that from the irradiated crystalline H$_2$S ice, commensurate with the increased decay rate of the former compared to the latter. Conversely, the electron irradiation of the crystalline SO$_2$ ice proved to be more conducive to the formation of SO$_3$ than did the irradiation of the amorphous phase. This is as expected for the low-fluence regime of the irradiation process (up to a fluence of about $5.3 \times 10^{16}$ electrons cm$^{-2}$), due to the amorphous SO$_2$ ice possibly resisting radiolytic decay. However, the greater abundance of SO$_3$ in the irradiated crystalline ices persists even beyond this fluence, despite the more rapid decay of amorphous SO$_2$ after this point. It should be noted, however, that after peaking at a fluence of about $5.5 \times 10^{15}$ electrons cm$^{-2}$, the SO$_3$ column density within the irradiated amorphous SO$_2$ ice also declines slightly (Figure 5). The concomitant loss of SO$_2$ and SO$_3$ from the ice during its irradiation suggests that sulphur is either being converted into a form which is not infrared active (e.g., atomic or allotopic sulphur) or is being desorbed or sputtered from the bulk ice. In either case, however, there is a fraction of the initially deposited sulphur that remains unobserved in the ice.

The sulphur budgets of each of the irradiated ices considered in this study are shown in Figure 6. It is possible to note that a loss of sulphur is observed upon supplying an initial electron fluence of $6.9 \times 10^{14}$ electrons cm$^{-2}$ in all of the ices apart from the amorphous SO$_2$ ice, and
that the quantity of unobserved sulphur as a fraction of that initially deposited continually grows during irradiation. In the case of the amorphous SO$_2$ ice, unaccounted for sulphur is only registered after a fluence of $2.7 \times 10^{16}$ electrons cm$^{-2}$ has been supplied, possibly due to the resistance of SO$_2$ to radiolytic dissociation as discussed earlier (de Souza Bonfim et al., 2017).

Although it is possible that electron irradiation resulted in the sputtering or desorption of the parent ice species, we consider this process to have likely been a relatively minor one. Previous work has shown, for example, that the reactive desorption of H$_2$S upon its formation as a result of the hydrogenation of HS on the surface of an interstellar ice analogue has a probability of 3% per hydrogenation event (Oba et al., 2018; Oba et al., 2019; Furuya et al., 2022), which is small from the perspective of an experimental study. Thus, if the electron-induced sputtering or desorption of sulphur-bearing molecules from the bulk ice is assumed to be negligible, then the fractions of unobserved sulphur shown in Figure 6 represent the sulphur present in an infrared inactive form, such as atomic sulphur or, more likely, residues composed of sulphur allotropes (Gomis and Strazzulla 2008). Our data therefore suggest an important point with regards to the production of such residues from pure H$_2$S and SO$_2$ ices: it is apparent that the irradiation of amorphous ices results in a greater abundance of sulphur residues than does the irradiation of crystalline ices. It should be noted, however, that the conversion of observable molecular sulphur to unobservable residues is very efficient in each of the considered ices, with amorphous H$_2$S, crystalline H$_2$S, amorphous SO$_2$, and crystalline SO$_2$ ices respectively showing 41, 25, 44, and 32% conversion of the initially deposited sulphur to residues at the end of irradiation (Figure 6).

**Implications for interstellar and Solar System chemistry**

The results of this present study are directly applicable to the astrophysical chemistry of sulphur. In dense molecular clouds in the interstellar medium, there is a known paucity of observed sulphur relative to its expected cosmic abundance (Tieftrunk et al., 1994; Ruffé et al., 1999). Recent studies have suggested that this depletion may be mediated by the Coulomb-enhanced freeze-out of sulphur cations onto negatively charged dust grains, whereupon they polymerise to yield sulphur-bearing residues and chains (Cazaux et al., 2022). Modelling efforts have suggested different explanations as to the major forms of sulphur in interstellar space: Vidal et al. (2017) suggested that, depending upon the age of the dense cloud, the majority of the sulphur exists either as unobservable atoms in the gas phase or as H$_2$S within icy grain mantles. Navarro-Almaida et al. (2020) also suggested the dominance of gas-phase sulphur atoms, whilst Laas and Caselli (2019) concluded that the majority of sulphur is found as organosulphur molecules within the icy grain mantles. Shingledecker et al. (2020) proposed that the major sulphur-bearing species in the condensed phase were sulphur allotropes along with SO$_2$ and OCS.

Nonetheless, it is expected that H$_2$S will be present within icy grain mantles as a result of the hydrogenation of adsorbed sulphur atoms. Furthermore, SO$_2$ is suspected to be present in such ices on the basis of its tentative detection (Roogert et al., 1997). Our results demonstrate that the irradiation of these ices by galactic cosmic rays (for which we have used an energetic electron beam as a simulant) could further contribute to the presence of sulphur residues, chains, and atoms in the dense interstellar medium and, by extension, could also account for a portion of the depleted sulphur in such regions. Moreover, such processes are likely to be more efficient when the dense cloud is either fairly young (i.e., it is still in its pre-stellar stage) or in those regions of the cloud which are not in proximity to heat sources such as protostars since, under such conditions, the interstellar icy grain mantles would not undergo crystallisation or thermal segregation of their molecular constituents and would thus remain amorphous.

Our results are also applicable to outer Solar System chemistry, particularly in the cases of the Galilean moons of Jupiter and of comets. SO$_2$ is the dominant molecular component of the surface ices and exosphere of the innermost of the Galilean moons; Io (Douté et al., 2001), and has also been detected as a component of the icy surfaces of Europa, Ganymede, and Callisto (Noll et al., 1997; Domingue et al., 1998; Noll et al., 1998). Surface temperatures on Io undergo quotidian cycles between 90–130 K, thus allowing for cycles of sublimation and condensation of the surface SO$_2$ frosts to be maintained (Bagenal and Dols 2020). During the Ionian day, warmer temperatures cause the sublimation of much of the surface SO$_2$ ice, resulting in the formation of a tenuous exosphere. At night, however, lower temperatures drive the collapse of much of the exosphere and re-condensation of the SO$_2$ to surface ices.

Given that Io orbits within the giant Jovian magnetosphere, its surface is continually exposed to ionising radiation in the form of energetic ions and electrons. The flux of 0.1–52 keV electrons at the surface of Io was given by Frank and Paterson (1999) to be $3.1 \times 10^8$ electrons cm$^{-2}$ s$^{-1}$, meaning the fluence delivered in our experiments would be delivered to the Ionian surface within 8.5 years. The temperature conditions at the surface of Io would lead one to assume that SO$_2$ ice is naturally found in the crystalline phase, and that, therefore, the radiation-induced formation of SO$_3$ should be reasonably efficient (Figure 5). However, our results also demonstrate that the prolonged irradiation of crystalline SO$_2$ ice at 20 K results in its
amorphisation, reducing the comparative yield of SO₃ in favour of refractory residues of allotropic sulphur (Figure 6). Such residues may contribute to the distinct colouration of Io (Carlson et al., 2007). It should be noted, however, that the extrapolation of radiation-induced amorphisation results acquired at low temperatures to higher ones may not be appropriate. For instance, although the amorphisation of crystalline H₂O is known to occur efficiently as a result of its irradiation at 20 K, this process has never been reported at temperatures >70 K (Mifsud et al., 2022c). The efficiency of the radiation-induced crystalline SO₂ ice amorphisation process at various temperatures (including those relevant to the surface of Io) should therefore be tested in future experiments.

Finally, we note that our results are also applicable to the chemistry occurring within the icy nuclei of comets. The recent ESA Rosetta mission to comet 67P/Churyumov-Gerasimenko revealed the presence of a number of sulphur-bearing molecules within its icy nucleus, including H₂S, SO₂, SO, OCS, CS₂, and S₂ (Rubin et al., 2020). As the comet approaches perihelion in its orbit around the Sun, thermally-induced crystallisation processes begin to out-compete space radiation-induced amorphisation. Correspondingly, the formation of allotropic sulphur residues via the irradiation of the H₂S and SO₂ cometary ice components by the solar wind may decrease slightly in line with the results presented in Figure 6.

Conclusion

In this experimental study, we have performed comparative and systematic electron irradiations of the amorphous and crystalline phases of H₂S and SO₂ ices using 2 and 1.5 keV electrons, respectively. We have shown that, in the case of H₂S, the amorphous parent ice decays at a more rapid rate than does the crystalline one, in a manner that is similar to that previously reported for CH₃OH (Mifsud et al., 2022b). This has been attributed to the presence of a more structured and extensive hydrogen bonding system in the crystalline phase compared to the amorphous phase, as well as the inherent lattice energy of the former, which require an additional energy input from the projectile electrons to be overcome before radiolytic chemistry may proceed. The formation of H₂S₂ as a product of the electron irradiation of H₂S occurs to a greater extent in the amorphous phase than in the crystalline phase, in part due to the greater abundance of radiolytically generated HS radicals.

The irradiation of the SO₂ ice revealed unexpected results. In the amorphous ice, two regimes are apparent: a low-fluence regime in which the ice is possibly resistant to radiolytic decay (potentially due to the favourable reformation of excited SO₂ after the dissociation of ground-state SO₂) and a high-fluence regime in which a slow exponential-like decay trend is observed. This contrasts greatly with the crystalline ice, for which a rapid exponential decay is first observed in the low-fluence regime followed by a slower decay (which is slower than that of the amorphous phase) in the high-fluence regime. Interestingly, the formation of SO₃ as a result of the irradiation of the crystalline ice was always greater than during the irradiation of the amorphous ice, possibly due to the initial resistance of the amorphous ice to radiolytic decay and its subsequent preferential formation of infrared inactive sulphur allotropes and residues.

We suggest that our results are important not only in the context of further investigating the phase-dependent radiation chemistry of astrochemical ices, which has thus far been overlooked in the literature, but also in further understanding the chemistry of sulphur in extra-terrestrial environments. Our characterisation of this phase-dependent chemistry is directly applicable to understanding the sulphur chemistry on the surface of Io, as well as in the icy nuclei of comets. Moreover, our calculated sulphur budgets for each of the irradiation processes considered in this study (which reveal the seemingly efficient formation of infrared inactive sulphur allotropes and residues) may aid in further constraining the exact molecular forms of sulphur in interstellar icy grain mantles and cometary ices. Finally, we conclude by noting that our experimental results further demonstrate the importance of incorporating ice phase as a factor when designing more complete ‘systems astrochemistry’ investigations (Mason et al., 2021).

Data availability statement

The raw data supporting the conclusion of this article will be made available by the authors, without undue reservation.

Author contributions

The experiment was designed by DVM and PAH and carried out by DVM, PH, STSK, ZJ, and BS. Data analysis was performed by DVM, who also wrote the manuscript. All authors were responsible for results interpretation and improvements to the manuscript.

Funding

The authors gratefully acknowledge funding from the Europlanet 2024 RI which has been funded by the European Union Horizon 2020 Research Innovation Programme under grant agreement No. 871149. The main components of the experimental apparatus were purchased using funding obtained from the Royal Society through grants UF130409, RGF/EA/180306, and URF/R/191018. Recent developments of the experimental set-up were supported in part by the Eötvös Loránd Research Network through grants ELKH IF-2/2019 and...
ELKH IF-5/2020. We also acknowledge support from the National Research, Development, and Innovation Fund of Hungary through grant No. K128621. DVM is the grateful recipient of a University of Kent Vice-Chancellor’s Research Scholarship. The research of ZK is supported by the Slovak Grant Agency for Science (grant No. 2/0059/22) and the Slovak Research and Development Agency (contract No. APVV-19-0072). SI acknowledges the Royal Society for financial support.

Acknowledgments

The authors would also like to thank Béla Paripás (University of Miskolc, Hungary) for his continued support and assistance.
