What’s new?

- Real-time continuous glucose monitoring (RT-CGM) improves neonatal health outcomes, with fewer large for gestational age infants, fewer neonatal intensive care unit admissions and a shorter neonatal length of hospital stay
- It is unknown whether the costs of implementing RT-CGM into NHS antenatal care, would be offset by the reduction in neonatal complications
- The approximately 3-fold higher costs of RT-CGM use, compared with self-monitoring of blood glucose (£1820 vs. £588), are offset by substantial cost savings, mainly through reductions in NICU admissions and a shorter duration of NICU stay
admissions (£3743) and the shorter duration of NICU stay (mean 6.6 vs. 9.1 days respectively). Sensitivity analyses showed that RT-CGM remained cost saving, albeit to lesser extents, across a range of NICU costs and durations of hospital stay, and with varying numbers of daily SMBG measurements.

**Conclusions** Routine use of RT-CGM by pregnant women with type 1 diabetes, would result in substantial cost savings, mainly through reductions in NICU admissions and shorter duration of NICU care.

**Introduction**

Type 1 diabetes during pregnancy is associated with increased risks of adverse outcomes such as pre-eclampsia, premature delivery, perinatal morbidity and admission to a neonatal intensive care unit (NICU) [1–4], which are at least partly attributable to suboptimal glycaemic control as measured by maternal glycated haemoglobin ($HbA_{1c}$) levels [5]. For this reason, the UK National Institute for Health and Care Excellence (NICE) has recommended that glycaemic control should be optimized before and during pregnancy in women with type 1 diabetes, with self-monitoring of blood glucose, at least four, and up to 10 times daily [6,7]. Despite frequent glucose monitoring optimal glucose control is often difficult to achieve due to pregnancy-related changes in insulin sensitivity and day-to-day variations in insulin pharmacokinetics with advancing gestation [8–10].

Real-time continuous glucose monitoring (RT-CGM) offers the potential to improve glycaemic control, compared with self-monitoring of blood glucose (SMBG), because it provides real-time data on changing glucose concentrations, thereby enabling users to take appropriate action in response to glucose fluctuations [11,12]. The potential value of this approach has been demonstrated in the Continuous Glucose Monitoring in Women with Type 1 Diabetes in Pregnancy Trial (CONCEPTT), in which the use of RT-CGM, in addition to SMBG, resulted in improvements in time in glycaemic target ranges during the second and third trimesters. This was accompanied by improved neonatal outcomes such as fewer large for gestational age infants, fewer NICU admissions >24hrs, less neonatal hypoglycaemia, and a shorter duration of hospitalization, among infants of mothers using SMBG and RT-CGM [11]. Importantly, the treatment effect of RT-CGM was comparable in women receiving insulin pump therapy, and in those receiving multiple daily injections (MDI). This is consistent with the experience of RT-CGM users outside of pregnancy, and suggests that the potential benefits of RT-CGM are applicable to a broad population of people with type 1 diabetes [13].

As RT-CGM and insulin delivery technologies are expensive, it is important to demonstrate the budgetary impact of these advancing technologies in clinical practice. Such evidence can be obtained through the use of budget impact models, which estimate the affordability of an intervention in a specific population over a short-term time horizon [14]. Our aim was to develop a budget impact model to estimate the costs and potential cost savings associated with the introduction of RT-CGM in pregnant women with type 1 diabetes.
<H1>Methods</H1>

A model was developed to estimate, from the perspective of National Health Service (NHS) England, the costs associated with the use of RT-CGM by pregnant women with type 1 DM. It assumes that RT-CGM is used throughout pregnancy for approximately 28 weeks (from 10-38 weeks gestation), and that neonates not admitted to a NICU stayed on a normal postnatal ward (Fig. 1). The model was constructed in Microsoft Excel, v1808 (Microsoft Corp, Redmond, WA, USA), and is available from the authors.

<H2>Model inputs</H2>

Model inputs are summarized in Table 1. Based on data from the 2014-2016 UK National Pregnancy Diabetes Audit, indicating 4323 pregnant women with type 1 diabetes over three years, we estimated that there were on average 1441 women per year throughout England [18]. Data on rates of complications (pre-eclampsia and NICU admission), durations of hospitalization or NICU stay, and frequency of glucose monitoring by RT-CGM or SMBG, were derived from CONCEPTT [11] and NICE guidance for the management of diabetes during pregnancy [6,7]. The indications for NICU admission and country-to-country NICU admission data were assessed posthoc after peer review.

Neonates admitted to a NICU also had a stay in the postnatal ward, either before or after NICU admission. The duration of these stays was recorded, and if this was less than 24 hours the corresponding cost of the postnatal ward admission was not included in the cost calculation; hence, this calculation can be considered conservative. Based on data from CONCEPTT, it was assumed that women would use a mean of four CGM sensors per month, giving a total of 28 sensors between 10-38 weeks gestation. In addition, based on the NICE guidelines on pregnancy [NG3] and management of type 1 diabetes [NG17] [6,7], it was assumed from that women would make an average of 10 finger stick measurements per day if they were using SMBG alone, and four if they were using SMBG together with RT-CGM.

Costs of managing complications and glucose monitoring were derived from the 2018/2019 NHS National Tariffs [16], NICE guidance [6,7], a published clinical trial of glycaemic control in paediatric ICUs [15], and commercial data from Medtronic Ltd (Watford, UK). NICE data show that the mean costs of normal and complicated deliveries are £1957 and £3357 respectively, and hence the incremental cost of a complicated pregnancy, compared with normal pregnancy is £1400 [19]. Because the NICE guidance states that women with pre-eclampsia undergo deliveries with complications and comorbidities [7], this incremental cost was multiplied by the proportion of women with pre-eclampsia. Costs associated with the management of diabetes (e.g., costs of insulin therapy) were not included in the model which focuses on glucose monitoring rather than mode of insulin delivery. All costs are reported as 2018 GBP (£).
Sensitivity analyses

The base case analysis assumed that 18% of deliveries would be complicated by pre-eclampsia [11], the mean cost of NICU was £3743 per day, and that the mean duration of NICU care when RT-CGM was used with SMBG, compared to SMBG alone (6.6 vs. 9.1 days, respectively) (unpublished CONCEPTT data). A number of sensitivity analyses were performed to determine the cost impact of varying different inputs. One-way analyses explored the impact of varying the proportion of complicated deliveries from 18% to 32%, and of varying the daily cost of NICU care from £3743 to £2400 or £3800. Two-way analyses investigated the potential cost impact of using between four and 12 blood glucose strips per day, and of durations of normal postnatal ward hospitalisation (excluding NICU) of between one and six days. It is now possible to use RT-CGM without SMBG, so the possibility of RT-CGM use with zero to four SMBG was assessed posthoc, after peer review.

Results

In the modelled population (n=1441), the total annual costs of glucose monitoring and the management of pregnancies and deliveries in women with type 1 diabetes were £23,725,648 when glucose monitoring was performed by SMBG alone (Table S1). These costs decreased to £14,165,187 when it was assumed that the entire modelled cohort used RT-CGM together with SMBG during pregnancy (Fig. 2). Hence, the potential cost saving resulting from RT-CGM use was approximately £9 560 461. The principal drivers of this saving were the daily cost of NICU care (£3743) and the shorter duration of NICU care when RT-CGM was used with SMBG, compared to SMBG alone (6.6 vs. 9.1 days, respectively).

The main reasons for NICU admission were preterm delivery (63%), neonatal hypoglycaemia treated with iv dextrose (56%), neonatal hyperbilirubinemia (54%) and respiratory distress (26%), with comparable indications for NICU admission when RT-CGM was used with SMBG, compared to SMBG alone. The UK sites had the highest proportion of NICU admissions (63%), followed by Canada (34%) with only one or none in Spain, Italy, Ireland and the USA (Table S2).

The impact of changes in complication rates and NICU costs on the potential cost savings achievable with RT-CGM was examined in sensitivity analyses. In the base case analysis, it was assumed that, in the absence of RT-CGM, 18% of deliveries would be complicated by pre-eclampsia. Increasing this proportion resulted in a progressive increase in the potential savings achievable with RT-CGM, which reached £9,842,896 with a complication rate of 32%. Further analysis showed that RT-CGM was still cost-saving when the daily cost of NICU care was reduced from the base case value of £3743 to £2400 (potential saving £5,444,736), and that the savings increased to £9,735,141 when the daily cost was increased to £3800 (Fig. S1).

Further sensitivity analyses examined the impact of SMBG strip use and length of non-NICU postnatal ward stay. The potential savings associated with RT-CGM use increased from approximately £9.1 million to £9.7 million when the mean number of daily finger stick measurements in the SMBG group was varied between four and 12, respectively (Table S3).
Furthermore, RT-CGM remained cost-saving, albeit to lesser extents, when the number of SMBG measurements in the RT-CGM users was increased from four to seven. In addition, greater cost savings were depicted when the number of SMBG measurements in the RT-CGM users was reduced to zero demonstrating the potential savings of newer CGM systems with reduced and/or no need for additional SMBG tests.

Similarly, decreasing the duration of postnatal (non-NICU) ward hospitalisation from three to one day, among RT-CGM users, increased the potential savings achievable (Fig. S2). The maximum potential saving was £11,145,546 when duration of non-NICU postnatal ward admission increased from three to six days in SMBG users and decreased from three to one days, among RT-CGM users (Table S4).

**Discussion**

This study has shown that the routine use of RT-CGM by pregnant women with type 1 diabetes could produce savings to the NHS of approximately £9.6 million, mainly through reductions in NICU admissions and a shorter duration of NICU stay. Furthermore, RT-CGM remained cost saving, albeit to lesser extents, across a range of NICU daily costs, durations of NICU stay and varied number of daily SMBG measurements. Our model highlights the impact of NICU admissions on the total costs associated with the management of type 1 diabetes during pregnancy. By contrast, the costs of postnatal ward admissions, in infants not admitted to NICU, and before or after NICU admission, account for smaller proportions of the total costs.

In this budgetary impact model, the cost of RT-CGM use from 10-38 weeks gestation was approximately three-fold higher than that of SMBG alone (£1820 vs. £588 respectively), with the assumption that 10 SMBG measurements would be made per day in SMBG users [7]. Nevertheless, sensitivity analyses showed that RT-CGM still remained cost saving, when SMBG measurements were reduced to less than four per day.

Furthermore, the observed savings may be under-estimates because we conservatively assumed that only 18% of pregnancies would be impacted by the additional costs associated with a complicated delivery (£3357 for complicated and £1957 for normal delivery [19]). Additional obstetric morbidities such as hypertensive disorders of pregnancy (any gestational hypertension, worsening of pre-existing hypertension) as well as maternal morbidity relating to large for gestational age birthweight (post-partum haemorrhage and perineal trauma) were not included with the incremental complicated delivery costs.

Data on the cost-effectiveness of RT-CGM during pregnancy are scarce [19]. A recent systematic review [21] identified only two studies that directly compared CGM with capillary glucose monitoring [22,23], neither of which included cost data. It is noteworthy that in CONCEPTT, the numbers needed to treat with CGM to prevent one neonatal complication were low; six for NICU admissions and large for gestational age, and eight for neonatal hyperglycaemia [11]. This suggests that the potential cost savings seen in the present analysis are achievable. Furthermore, more than 50% of pregnant women in CONCEPTT were using multiple daily injections [11], and hence the costs of insulin treatment would have been lower.
than with pump therapy. By contrast, in the Juvenile Diabetes Research Foundation study, approximately 90% of adults with type 1 diabetes, were using insulin pump therapy [24]. Importantly, clinical efficacy of RT-CGM in women using insulin pump therapy and multiple daily injections was comparable, although rates of NICU admission >24 hours were higher among insulin pump users [25]. However, the costs of insulin therapy were not included in our model, so we cannot draw conclusions about the potential costs of RT-CGM in women using pumps or multiple daily injections.

Because type 1 diabetes during pregnancy is associated with increased risks of serious pregnancy complications such as congenital abnormalities, stillbirth, and neonatal mortality, it imposes particular clinical, societal and financial burdens on healthcare systems [26]. Large for gestational age remains the commonest complication, affecting half of all infants born to mothers with type 1 diabetes, and increases risk for obstetric complications including shoulder dystocia, instrumental and/or operative delivery and post-partum haemorrhage [27]. These costs are considered only in the duration of NICU and postnatal hospitalisation. Recent data confirm that the risk of adolescent obesity is 1.5 times higher in infants born large for gestational age [28], suggesting that the acceleration of BMI and sustained obesity persist throughout childhood and adolescence. The longer-term costs associated with childhood overweight and obesity attributable to large for gestational age birthweight in type 1 diabetes pregnancy are unknown.

Strengths of the present study include the use of outcome data from a multicentre randomized controlled trial, robust sensitivity analyses and the use of contemporary National Diabetes Pregnancy data in the model. Approximately two-thirds of NICU admissions occurred in the UK making these data representative of the factors affecting NICU admission in the NHS. As well, the model inputs have been varied to reflect different scenarios of SMBG use and NICU costs, with RT-CGM found to be consistently cost saving. The reductions in large for gestational age neonates, neonatal hypoglycaemia and NICU admissions in RT-CGM users were generalizable across 31 centres from the UK, Canada, Spain, Italy, Ireland and the USA, so while there is no reason to assume that the potential for cost savings would vary substantially in different healthcare settings, they may be most applicable in settings with high NICU admission rates. The study has additional limitations. The modelled population is restricted to England, which may limit the generalizability of our findings, although pregnancy outcome data are comparable to studies from other Northern European, Canadian and USA healthcare settings [1,2,4,5,29,30]. A further potential limitation is that costs associated with the treatment of diabetes, such as diabetes educator time and costs of insulin therapy, were excluded from the model. As a result, it is not possible to determine whether, or to what extent, these costs affect the RT-CGM cost savings. Furthermore, the RT-CGM used during CONCEPTT has been superseded by newer CGM systems with a longer sensor lifespan. Recent improvements in sensor accuracy and reduced need for pre-meal SMBG and/or additional calibration tests, also mean that the current costs of glucose monitoring with modern CGM devices may now be lower.

The results of this study have important implications for clinicians and policy makers. Current NICE guidance recommends that women with diabetes should aim to achieve an
HbA1c level of <48 mmol/mol (<6.5%) [6], but achieving this level of control throughout pregnancy is often difficult. It was achieved by only 40% of women with type 1 diabetes in England and Wales, with substantial variability across different maternity clinics [26]. By contrast, the NICE target HbA1c was achieved by 66% of women in CONCEPTT, with no heterogeneity across differing baseline maternal HbA1c levels or across countries. Pregnant women are often amongst the early adopters of advanced diabetes technologies, with data from the USA T1D Exchange clinic registry participants suggesting that approximately one third used CGM and three quarters used insulin pump therapy [29]. The Belgian healthcare authorities have authorized reimbursement of RT-CGM for insulin pump users with T1D treated in selected specialized diabetes centres. Initial data from over 500 users including 66 women who were pregnant and/or planning pregnancy suggested potential for sustained improvements in glucose control for up to 12 months [30]. Inclusion of diabetes technology use (both RT-CGM and insulin pump therapy) as a key metric in national and international Diabetes Pregnancy datasets is needed to determine whether the clinical and cost-effectiveness demonstrated in CONCEPTT can be translated into real-world NHS clinical settings.

In conclusion, our results suggest that the higher costs of RT-CGM, compared with SMBG alone, are offset by savings in NICU care. The cost savings associated with RT-CGM use are achieved mainly through reductions in NICU admission rates, and in the shorter length of NICU stay. This is an important message for clinicians and healthcare providers, given that 40% of infants born to mothers with type 1 diabetes are admitted to NICU [26]. Routine use of RT-CGM by pregnant women with type 1 diabetes would result in substantial cost savings to the NHS, and probably to other healthcare systems. Recent improvements in sensor accuracy and duration mean that current RT-CGM use may result in more substantial cost savings.

**Funding sources**

Funding for the development of the economic model reported here was provided by Medtronic. CONCEPTT was funded by JDRF grants #17-2011-533, and grants under the JDRF Canadian Clinical Trial Network (CCTN), a public-private partnership including JDRF and FedDev Ontario and supported by JDRF #80-2010-585. Medtronic supplied the CGM sensors and CGM systems at a reduced cost. HRM is supported by Tommy’s charity.

**Competing interests**

DSF reports advisory/speaker fees from Medtronic, Novo Nordisk and Dexcom. HRM reports personal fees from NovoNordisk, Roche, Medtronic, Abbott Diabetes Care, outside the submitted work. HRM sits on the Medtronic European Scientific Advisory Board. AS is a full-time employee of Medtronic. SDP is a full-time employee of Medtronic, and owns stocks in the company.

### RT-CGM with SMBG

**RT-CGM costs**

- Transmitter (replaced annually) £350 Manufacturer’s data*
- Sensor unit cost £52.50 Manufacturer’s data
- Number of sensors per month 4 CONCEPTT [11]
- Number of sensors per pregnancy † 28
- Total sensor cost per pregnancy £1470
- Total RT-CGM cost per pregnancy £1820

**SMBG costs**

- Mean number of fingerstick measurements per day 4 NICE guidance [6,7]
- Cost per glucose strip £0.30 British National Formulary [17]
- Cost per day £1.20
- Cost per month £33.60
- Cost per pregnancy £235.20
SMBG costs

Mean number of fingerstick measurements per day 10

Cost per glucose strip £0.30 British National Formulary [17]

Cost per day £3
Cost per month £84
Cost per pregnancy £588

RT-CGM, real-time continuous glucose monitoring; SMBG, self-monitoring of blood glucose; NICU, neonatal intensive care unit; CONCEPTT, Continuous Glucose Monitoring in Women with Type 1 Diabetes in Pregnancy Trial; NICE, National Institute for Health and Care Excellence.

*Manufacturer’s data provided by Medtronic Ltd (Watford, UK).

†Assumed that RT-CGM is used for 7 months (from 10 to 38 weeks’ gestation) per pregnancy based on CONCEPTT [11].

‡Unpublished CONCEPTT data (provided by HR Murphy and DS Feig).
