Reference genes

ABSTRACT

Microalgae are of substantial biotechnological interest due their polyphyletic nature which grants them access to a wide array of high-value metabolites. The inherent genetic diversity of microalgae combined with their metabolic plasticity when grown using different trophic and illumination strategies necessitate the establishment of a reference knowledge base. In the present study we present a detailed characterisation of the combined effects of wavelength selection and trophic strategy on the growth kinetics and gene expression profile of the model microalgae *Chlamydomonas reinhardtii* grown under moderate to high light intensity (400 μmol m⁻² s⁻¹). The aim is twofold: (a) to establish a list of reliable housekeeping genes valid for quantitative comparisons across several combinations of different wavelengths and trophic strategies and (b) to enable the investigation of the response of central carbon metabolic pathways under these process conditions. White, blue and red light emitting diodes (LEDs) were used to grow pH controlled photo- and mixo-trophic cultures over a period of 136 h in batch mode. A panel of 10 candidate genes, along with biomass growth rate and pigment content were dynamically monitored across all conditions. Statistical analysis identified genes (acetyl-CoA carboxylase subunit α and photosystem I reaction centre subunit II) with less variability observed in their expression levels across the entirety of conditions evaluated compared to housekeeping genes often referred to in literature (receptor of activated protein kinase C and ribosomal protein (large subunit) 19). Further analysis of gene expression profiles revealed substantial differences in response to changes in both wavelength selection (upregulation of ribulose bisphosphate carboxylase small subunit under red phototrophic growth) and trophic strategy (upregulation of malate synthase from phototrophic to mixotrophic conditions). The systematic approach used to establish reliable reference genes presented herein enables robust comparisons of cellular responses across different conditions to better understand algal metabolism and improve process performance.

1. Introduction

Freshwater microalgae, like *Chlamydomonas reinhardtii*, have evolved an extensively versatile metabolism that increases their chances of survival in diverse environmental conditions in the presence (mixotrophy) or absence (autotrophy) of a readily available source of nutrients [1]. Due to this metabolic plasticity, and despite significant research efforts, our knowledge of algal metabolism remains nascent, relative to other crops, and our control over biomass composition remains rudimentary [2]. One of the main reasons that fully understanding algal metabolism and how it responds to varying environmental and bioprocessing conditions is far from trivial is the uniqueness of incident light as a critical process parameter. The effects of light on microalgal physiology are mediated by a variety of specialised, light harvesting and light sensing molecules. Chlorophylls, carotenoids, rhodopsins, phototropins and cryptochromes each have a unique absorption spectrum and are involved in different cellular processes like photosynthesis, phototaxis [3] or cell cycle control [4,5].

In addition, light in and of itself is complex in nature as it can vary in terms of intensity, photoperiod and spectral composition. Light intensity has a well documented and characterised positive effect on biomass growth both under phototrophic and mixotrophic conditions [6]. However, excessively high light intensities have been shown to trigger stress responses, like carotenoid production, in a number of algal species [7,8] or even completely inhibit growth (photoinhibition) [9]. Phototrophic studies on biomass growth of *C. reinhardtii* have shown that below saturating light levels (25–100 μmol m⁻² s⁻¹), illumination with red and red-blue light can achieve a higher biomass yield on
photon absorption. Consequently, illumination at wavelengths considered to be suboptimal due to their relatively low specific absorption rate (e.g. illumination with yellow and warm white light) has been found to yield higher biomass yields than red or blue light at high light intensities [11].

The advent of light emitting diodes (LEDs) has enhanced our ability to accurately control several properties of incident light, beyond intensity, and investigate their effects on biomass growth and biochemical composition [12]. This has enabled in depth investigations of the effects of the frequency and duration of light/dark cycles, spanning timescales from milliseconds to hours (diel-cycle) [13–15]. Studies on the impact of light quality on biomass composition, primarily focused on pigment and/or lipid content in specialised producer species like Haematococcus pluvialis and Phaeodactylum tricornutum [16], have shown a variety of possible responses across species. Therefore, there is a need to understand the diverse and complex effects of the spectral composition of incident light on microalgal physiology and metabolism.

Associating gene expression profiles with changes in microalgal physiology under narrow band illumination can help unravel the specific effects of discrete regions of the photosynthetically active radiation (PAR) region of the visible light spectrum (400–750 nm). However, relative quantification of reverse transcription-quantitative real time polymerase chain reaction (RT-qPCR) measurements requires the existence of a set of reference genes with stable expression profiles across a variety of culture conditions. A number of studies have previously proposed candidate reference genes for *C. reinhardtii* with no clear consensus available in the literature due to the limited number of experimental conditions examined in each study [17–19]. A comprehensive study of the stability of four candidate reference genes under nitrogen deprivation both in photoautotrophic and mixotrophic conditions was recently published [20], however is limited to only white light illumination. An extensive transcriptomic analysis of *C. reinhardtii* gene expression under a variety of nutrient depletion conditions has been recently published [21].

Given the biotechnological potential of triggering desired responses in a microalgal culture by utilising a tailored spectral composition, this study investigates the effects of wavelength selection and trophic strategy on gene expression in *C. reinhardtii*. The genetic responses elicited by monochromatic LEDs with narrow peak intensities at the two extremes of the PAR range (Blue, 440-480 nm and Red, 640-670 nm) under phototrophic and mixotrophic conditions were compared against white light control cultures. A set of 10 candidate reference genes was compiled from literature and their stability was assessed across all 6 experimental conditions. The novel reference genes identified herein, coupled with dynamic biomass and pigment content measurements, were used to evaluate the effect of wavelength and trophic strategy induced changes at key metabolic nodes. Finally, the expression levels of promoter genes and/or 5′–/3′-untranslated regions (5′–/3′-UTR) previously targeted for the expression of recombinant proteins in *C. reinhardtii* were characterised to discern favourable illumination conditions and trophic strategies.

2. Materials and methods

2.1. Organism and growth conditions

*Chlamydomonas reinhardtii* wild-type strain 11/32C was obtained from the Culture Collection of Algae and Protozoa (CCAP, Scotland). *C. reinhardtii* 11/32C was grown in M8a media [22] supplemented with 7.49 mM(g L−1) of ammonia as the Nitrogen source [23]. Mixotrophic cultures were grown in modified M8a medium (referred to as M8a.Ac) supplemented with 17 mM of acetic acid (Sigma-Aldrich®, UK) and 20 mM Tris base (Sigma-Aldrich®, UK). Seed cultures were inoculated from streaked agarose plates in 500 mL of M8a medium and grown in an ALGEM Environmental Modelling Labscale Photobioreactor (Algenuity, UK) at 25 °C with pH controlled at 7 ± 0.1. Incident light intensity for all seed cultures was linearly increased during the first 48 h until 400 μmol m−2 s−1 and was subsequently kept constant for up to 84 h. Cultures for the experimental work presented herein were inoculated from seed cultures at a starting concentration of 1×10⁶ cells mL−1 in 500 mL of either M8a or M8a.Ac media and maintained under constant illumination at 400 μmol m−2 s−1 throughout the experiment. The experiments were performed at 25 °C, under continuous aeration (75 cm³ min⁻¹) provided through an HD-601 aquarium pump (Hidom, China). 5% CO₂-enriched air was automatically supplied on demand (75 cm³ min⁻¹) to maintain pH at 7 ± 0.1. In the remainder of the text, the following abbreviations are used to describe wavelength selection (W: white light, B: blue light 440-480 nm, R: red light 640-670 nm) and trophic conditions (A: phototrophic growth in M8a, X: mixotrophic growth in M8a.Ac).

2.2. Chlorophyll quantification

1 mL samples were collected post inoculation and after 48 h of culture. The samples were spun down at for 2 min at 5000 g (Eppendorf 5415, Eppendorf, UK) under constant temperature (4 °C). The supernatant was aspirated, and pigments were extracted by re-suspending the cell pellet in 1 mL of dimethylformamide (DMF, Sigma-Aldrich®, UK) while avoiding direct exposure to light. The resuspended pellets were centrifuged for 2 min at 10,000g under constant temperature (4 °C) and the supernatant was transferred to a solvent resistant BRAND® UV cuvette (Merck, Germany). Chlorophylls A and B were quantified through absorbance readings at 647 and 664 nm respectively according to their maximum absorption coefficients [24].

2.3. Cell size distribution

Cell size distribution was measured with a CAST® TTC Cell Counter and Analyser System (OmiLife Science, Germany) as previously described [25]. Briefly, 50 μL of culture were diluted in 10 mL of Casyton® buffer (OmiLife Science, Germany), mixed by inversion and immediately processed.

2.4. Ribonucleic acid (RNA) extraction

Samples containing 5×10⁶ cells were centrifuged for 5 min at 12,000 g (Eppendorf 5415, Eppendorf, UK) under constant temperature (4 °C). The supernatant was aspirated and discarded, and the cell pellet was stored at −80 °C for up to 4 months until further processing. RNA extraction was performed in 2 mL MaxTract High Density Tubes (Qiagen, Netherlands) using TRIzol® (Invitrogen, USA) and following the manufacturer’s instructions. GlycoBlue™ Coprecipitant (Invitrogen, USA), dissolved in 50 μL of RNase-free TE buffer (Sigma-Aldrich®, UK), was used to stain the nucleic acid pellet. Contaminating gDNA was removed with RNase-free DNase (Qiagen, Netherlands) according to the manufacturer’s protocol. RNA integrity was assessed with a 1% ethidium bromide stained agarose gel in TBE buffer. RNA purity and concentration were assessed using a NanoDro spectrophotometer (Thermo Fisher, USA). Ratios of absorbance readings at 260/280 nm and 230/260 nm ratios displayed little variability (2 ± 0.1) and indicated a lack of phenol contamination from the TRIzol based extraction.

2.5. Primer design

Gene primers for RT-qPCR were designed following the Minimum Information for Publication of Quantitative Real-Time PCR Experiments (MIQE) guidelines. Gene sequences were obtained from the *Chlamydomonas reinhardtii* genome v5.5 in the Phytozome database [26]. A custom set of parameters prioritising primer pairs that span intron-exon junctions was used to select primer sequences in primer3 [27].
quality was assessed with PCR Primer Stats [28]. Melt curve analysis with no template controls (NTC), no reverse transcription controls (NRT) and positive controls was used to ensure each primer pair gave rise to a single, well-defined peak from extracted RNA. Serial and linear dilutions were used to establish the log-linear dynamic range for each primer pair and primer efficiency. Starting RNA and primer mix concentrations were optimised over three orders of magnitude (1.5–150 ng μL⁻¹ and 0.9–90 μM respectively).

2.6. Quantitative reverse transcription polymerase chain reaction (RT-qPCR)

RT-qPCR was carried out with a Luna® Universal One-Step RT-qPCR Kit (New England Biolabs, USA) on a CFX 96 connect Real-Time PCR System (Bio-Rad, USA). Individual RT-qPCR reactions had a total volume of 20 μL made up of 10 μL Luna Universal One-Step Reaction Mix (2×), 1 μL Luna WarmStart® RT Enzyme Mix (20×), 2 μL forward and reverse primer mix (9 μM), 5 μL RNA (75 ng) and 2 μL Nuclease-Free Water. Thermal cycling was programmed according to the kit manufacturer’s instructions. In short, 1 cycle of reverse transcription at 55 °C for 10 min followed by 1 cycle of initial denaturation at 95 °C for 1 min and 40 cycles of denaturation and extension at 95 °C (for 10 s) and 60 °C (for 30 s) respectively. A 60–95 °C melt curve was generated to evaluate primer specificity and gDNA contamination.

2.7. Reference gene selection and statistical analysis

A panel of 10 candidate reference genes was compiled from literature (Table 1). A set of six diverse experiments including combinations of three different wavelengths and two different trophic strategies was designed to evaluate stability in expression levels. Expression levels of the candidate genes (Table 1) were measured by RT-qPCR with samples taken 16, 48 and 136 h hours post inoculation and analysed with the qBase+ software package (Biogazelle). The geNorm algorithm [29,30] was used to calculate the coefficient of variation of the normalised reference gene expression levels (CV) and the geNorm stability M-value (M) was used to rank candidate reference genes from least to most stable. Gene expression data were further analysed by performing 3 (W, R, B) by 2 (A, X) factorial ANOVAs to evaluate main and interaction effects of wavelength and trophic strategy on the average relative expression of each gene of interest. Multiple comparisons with Benjamini-Hochberg correction were performed in the statistical software R (version 3.6.1).

3. Results

The scientific literature is rich with studies on the phenotypic and metabolic response of C. reinhardtii to different intensities and qualities of light. Specifically in terms of light intensity, studies have been conducted under low (10–100 μmolph m⁻² s⁻¹) [20], moderate (100–700 μmolph m⁻² s⁻¹) [31,32] or high (>700 μmolph m⁻² s⁻¹) [11,33,34] light intensities. In recent years, studies with a focus on industrial applications such as the production of speciality chemicals or the expression of recombinant proteins have focused on moderate and high light intensities [11,33,34]. In the present study, a moderate light intensity of 400 μmolph m⁻² s⁻¹ was used for all culture conditions. Consequently, caution should be used when extrapolating the conclusions discussed below to significantly higher or lower light intensities.

3.1. Expression stability

Relative quantification of gene expression via RT-qPCR requires the determination of one (or more) reference genes which are expected to maintain a stable expression level across all experimental conditions examined [35]. The panel of candidates genes (Table 1) investigated in the present study reflects three distinct selection criteria: (a) genes extensively used as reference genes in relevant scientific literature (RACK1, RPL19, CH3-I and RPS10 [19,36–39]), (b) genes with functional similarities to widely used reference genes (PSRP-I, psd and ATPD [40]) and, novel in this study, (c) genes involved in central carbon metabolism due to its vital role in cellular function under most relevant experimental conditions (DLA3, ACX1 and STA1). Gene expression was measured at three time points (16, 48 and 136 h post inoculation) for each of the six possible combinations of wavelength (W, R, B) and trophic strategy (A, X).

Raw RT-qPCR data is evaluated in terms of quantification cycle (Cq), which is the number of amplification cycles required for a RT-qPCR reaction’s fluorescence to surpass a defined threshold. This is inversely correlated to the specific cDNA template present in the reaction. The 10 genes evaluated displayed a wide range of average Cq values (Cq) with ATPD at the low end (Cq = 14) and DLA3 at the high end of the range (Cq = 22). An overview of all Cq ranges measured for candidate reference genes under all experimental conditions examined in this paper is presented in Fig. 1. Interestingly the Cq value for ATPD was also found to have lowest variance across all conditions while the Cq values for PSRP-I, chosen for its similarity to canonical ribosomal protein genes utilised as reference genes throughout literature, varied significantly between conditions. Given its exclusively plastidic localisation, it is possible that ribosomal activity in the chloroplast is, at least partially, regulated at the transcriptional level in response to changes in the quality of incident light.

Prior to the development of sophisticated data analysis algorithms and the widespread availability of real-time PCR systems, relative quantification was primarily based on a single reference gene derived either from literature or through simple, yet effective, log-linear models (ΔΔCq) [41,42]. However, current state of the art for comparison of gene expression across widely varying conditions or cell lines involves the use of sophisticated algorithms that employ two or more genes to normalise expression across widely varying conditions or cell lines [43]. The geNorm algorithm, used in the present study, has been successfully applied to a wide variety of organisms [18,44,45]. The algorithm uses pairwise variation (Vn/n+1) to evaluate the number of reference genes required to achieve an accurate normalisation factor (M) which will remain stable across all experimental conditions and cell lines studied [29,30]. Analysis of the results indicated that ACX1 and psd form the most stable pair of genes with a V2/3 value lower than the recommended threshold (<0.15) [29] indicating that additional reference genes are not required.

ACX1 encodes the α-carboxyltransferase subunit of the multimeric acetyl coenzyme A (acyt-1-CoA) carboxylase (ACCase) and has been shown to be expressed in co-ordination with the other subunits in Arabidopsis thaliana [46] and C. reinhardtii [47]. While significant variations in the expression levels of both the α- [20,47] and the β- [48] carboxyltransferase subunits have been reported in nitrogen starved cells, expression levels of ACX1 have been shown to remain stable under nitrogen replete conditions, in agreement with the findings in the present study.

The psd gene encodes subunit II of photosystem I (PSI), an essential component for PSI accumulation in Arabidopsis thaliana [49] and key to the efficient functioning of PSI in Synechocystis sp [50]. A highly expressed constitutive gene, its promoter element has always remained relevant in recombinant protein expression studies in C. reinhardtii [51,52]. Light intensity and light quality have been shown to affect the pigment content and composition of microalgal cells but, to the extent of our knowledge, none of the available studies tested the expression levels of psd under monochromatic illumination. It is not particularly surprising that a gene expressing an essential PSI subunit presents robust expression across the conditions studied in the present study as essential photosynthetic components are commonly controlled by post-translational regulatory processes such as episty of synthesis (CES) [53].

3.2. Growth and gene expression under different wavelengths and trophic strategies

Batch cultures of C. reinhardtii 11/32C were grown for 136 h under constant illumination at three different wavelengths (W, R, B) using media with (X) and without (A) a readily available organic carbon source. Daily biomass measurements (OD 750 nm) were used to estimate growth rate during the exponential growth phase (μexp, Table 2, Fig. S1). In agreement with findings from other studies [11], white light illumination was found to have the highest growth rate in both trophic strategies. Interestingly, under the constant environmental conditions considered in the present study (pH, temperature and light intensity), the presence of an organic carbon source had a significant impact on biomass growth only under blue light illumination. In contrast, the addition of a carbon source under white light illumination (WX) resulted in 5% reduction in μexp compared to (WA). The rate of acetate consumption in mixotrophic cultures (qAc, Table 2) was nearly identical under all studied wavelengths irrespective of the observed biomass growth rate. Acetate was fully extinguished from the media within the first 48 h post inoculation in all mixotrophic conditions.

Table 2
Summary of macroscopic growth parameters of C. reinhardtii cultured under different illumination and trophic strategies. Values calculated based on biomass and acetate concentrations between t1 = 0 h and t2 = 48 h. W: white LED light; R: red LED light 640-670 nm; B: blue LED light 440-480 nm; A: phototrophic growth in M8a; X: mixotrophic growth in M8a.Ac; μexp: observed biomass growth rate (hour−1); qAc: observed acetate uptake rate (hour−1).

|        | WA | RA | BA | WX | RX | BX |
|--------|----|----|----|----|----|----|
| μexp (hour−1) | Flask 1 | 0.076 | 0.054 | 0.042 | 0.064 | 0.055 | 0.056 |
| Flask 2 | 0.069 | 0.056 | 0.040 | 0.074 | 0.058 | 0.050 |
| qAc (mM h−1) | Flask 1 | – | – | – | 0.363 | 0.369 | 0.370 |
| Flask 2 | – | – | – | 0.361 | 0.370 | 0.370 |
The expression levels of a panel of genes selected based on their metabolic function (Table 1) were measured and analysed for each of the six experimental conditions described above. All reported gene expression levels were calculated relative to the expression of the two most stable reference genes identified in Section 3.1 (ACX1 and psaD). Gene expression levels for central carbon metabolism genes were estimated by averaging values obtained from two samples taken during the exponential growth phase (16 h and 48 h). The expression level of promoter genes was evaluated at three different time points (16 h, 48 h and 136 h) throughout the culture. In the sections that follow, gene expression results are presented and discussed grouped by metabolic pathway.

3.3. Photosynthesis

The ribulose-1, 5-bisphosphate carboxylase oxygenase (RUBISCO) found in *C. reinhardtii* is a hexadecamer composed of eight small subunits (SS) and 8 large sub-units (LS). Two variants of the small subunit of RUBISCO have been identified in the *Chlamydomonas* nuclear genome (RBCS1 and RBCS2) [54]. While their peptide products differ by only four amino acids and are functionally redundant [54], their expression is dependent both on trophic strategy and the presence or absence of light [55,56]. The primer pair designed and used in this study (Table 1) amplitifies both sub-unit variants (RBCS1 and RBCS2) to enable the evaluation of overall RBCS expression irrespective of individual sub-unit related dependences (Fig. 2A). Wavelength selection had a statistically significant effect ($p < 0.01$) on the average expression level of RBCS with average expression levels under red light (R) being significantly higher compared to both white (W) and blue (B) light in both trophic conditions (A, X). In addition, the average RBCS expression in cultures grown under blue light (B) was significantly higher ($p < 0.05$) than those grown under white light (W) in both trophic conditions. It is worth noting that the macroscopically observed biomass growth rate (Table 2) does not appear to be strongly correlated with RBCS expression levels. Under both trophic strategies, (R) illuminated cultures displayed statistically significant higher RBCS expression levels than (W) illuminated cultures, however resulted in lower growth rate values. Similarly, low levels of RBCS expression measured in B and W cultures resulted in substantially different growth rates (Table 2). These differences were observed in both trophic conditions and the presence of an external carbon source did not seem to have a significant impact on RBCS expression levels.

In order to further understand the implications of these results, cell size distribution during the mid-exponential growth phase (48 h) was measured for all conditions (Fig. 4). In both trophic conditions examined, cells grown under constant red light illumination had a smaller average diameter, while cells grown under constant blue light illumination had a larger average diameter when compared to control cultures grown under white light. The growth rate data (Table 2), calculated using optical density measurements (750 nm), coupled with the cell size distribution data (Fig. 4) indicate that wavelength selection has an impact on the cell cycle [57,58]. The balanced combination of long- and short-wavelengths making up white light results in the fastest biomass production under both phototrophic (WA) and mixotrophic (WX) conditions. Additionally, an average cell cycle length is maintained and consequently cell size remains in-between the smaller cells produced by (R) and the larger cells produced by (B) in both trophic strategies. The upregulation of RBCS under red light indicates an increased need for energy generation, likely required to operate a shorter cell cycle and maintain a rapid duplication rate. On the other hand, cells grown under blue light had lower RBCS expression levels (Fig. 2A), a lower apparent growth rate (Table 2) and the largest observed average cell diameter (Fig. 4). These results suggest that blue light illumination leads to larger cells on average with an longer or arrested cell cycle while red light illumination leads to smaller, rapidly dividing cells. However, in terms of overall biomass yield (in gDCW/L) both extremes of the PAR spectrum underperform when compared to white light illumination.

Chlorophyll (Chl) a/b measurements (Fig. 3) revealed a statistically significant higher Chl a/b ratio in cultures grown under red light (RA, RX). The Chl a/b ratio has been previously inversely linked to PSII antenna size due to Chl b’s preference for binding to peripheral antenna complexes [59]. Moreover, in agreement with previous studies [10], the specific amount of Chl b per pg of biomass was significantly lower under red light illumination. Given that incident light intensity was kept constant, this difference in Chl a/b ratio may reflect changes in the light harvesting apparatus in response to the differing wavelength distributions. The distribution data (Fig. 4) indicate that wavelength selection has a larger average diameter when compared to control cultures grown under white light. The growth rate data (Table 2), calculated using optical density measurements (750 nm), coupled with the cell size distribution data (Fig. 4) indicate that wavelength selection has an impact on the cell cycle [57,58]. The balanced combination of long- and short-wavelengths making up white light results in the fastest biomass production under both phototrophic (WA) and mixotrophic (WX) conditions. Additionally, an average cell cycle length is maintained and consequently cell size remains in-between the smaller cells produced by (R) and the larger cells produced by (B) in both trophic strategies. The upregulation of RBCS under red light indicates an increased need for energy generation, likely required to operate a shorter cell cycle and maintain a rapid duplication rate. On the other hand, cells grown under blue light had lower RBCS expression levels (Fig. 2A), a lower apparent growth rate (Table 2) and the largest observed average cell diameter (Fig. 4). These results suggest that blue light illumination leads to larger cells on average with an longer or arrested cell cycle while red light illumination leads to smaller, rapidly dividing cells. However, in terms of overall biomass yield (in gDCW/L) both extremes of the PAR spectrum underperform when compared to white light illumination.
constant across all experimental conditions, this further supports the hypothesis stated above, that red light illumination leads to a shortened cell cycle. High values of the Chl a/b ratio, coupled with a smaller antenna [59] and average cell size (Fig. 4) result in reduced surface area for absorption of photons and increased photosynthetic efficiency as well as reduced mutual shading across the light path. These effects combine to increase the proportion of cells in the culture receiving enough light to maintain a high growth rate. Consequently, the implied increase in light utilisation efficiency under red light illumination would result in an increased demand for Calvin-Benson cycle (CBC) enzymes like RUBISCO, and potentially increased gene expression as has been observed in the present study (Fig. 2A), to fulfil the increased demand. When considering the monochromatic conditions of this study in isolation, there is a strong positive correlation between biomass growth rate and RBCS expression in the autotrophic conditions that is lost in the mixotrophic regime. This suggests that the availability of an organic carbon source and the resulting switch to mixotrophic metabolism reduce the relevance of photosynthetically generated metabolic resources in biomass growth rate maximisation. This is not apparent in growth under white light, possibly due to its more varied spectral distribution resulting in optimal phototropic growth at a lower light utilisation efficiency compared to monochromatic illumination.

3.4. Acetyl coenzyme A catabolism

Acetate uptake rates (Table 2) were found to be independent of wavelength selection and biomass growth rate. However, when comparing biomass growth across trophic strategies for the same wavelength selection, differences in metabolic behaviour can be observed. In cultures grown under constant white light (WA, WX) and red light (RA, RX) illumination, the addition of acetate as a carbon source resulted in a relatively small change in biomass growth rate (Table 2). This suggests that under appropriately controlled conditions phototrophic growth under each of these two lights is nearly optimal. It seems that introducing an organic carbon source under these conditions does not result in an increased rate of biomass production. In contrast, for cultures grown under blue (BA, BX) light, the addition of acetate resulted in a substantial increase of the growth rate. Interestingly, RBCS expression levels remained similar across the different trophic strategies (WA, WX, RA, RX and BA, BX; Fig. 2A), indicating no drastic change in the rate of carbon fixation from photosynthesis. Therefore, under white and red illumination the additional carbon uptake in the form of acetate must be assimilated through a different metabolic pathway, one not directly linked to biomass growth. The presence of acetate is known to trigger a reconfiguration of *C. reinhardtii* metabolism as the inorganic carbon fixation of photosynthesis is complimented by the organic carbon assimilation of acetate via its conversion to acetyl-CoA [60].

In nutrient replete mixotrophic conditions acetyl-CoA is preferentially produced in a single enzymatic step catalysed by acetyl-CoA synthase (ACS) [61]. ACS homologs have been identified in several cellular compartments (ACS1 - cytosol ACS2 - plastid, ACS3 - glyoxysomes and mitochondria) [62,63]. Consequently, this metabolic plasticity enables the cells to repurpose assimilated acetate to drive different metabolic pathways by channelling it to the appropriate cellular compartments. As can be seen in Fig. 5A, Acetyl-CoA is primarily utilised in fatty acid chain formation (cytoplasm), in the glyoxylate cycle (glyoxysome) and in the TCA cycle (mitochondria). Differences in transcriptional activity between photoautotrophic and mixotrophic metabolism may elucidate the fate of acetate derived carbon assimilated during mixotrophic growth. Therefore, the expression level of enzymes exclusive to each of the three main metabolic pathways that consume acetate-CoA was evaluated for all experimental conditions.

3.4.1. Tricarboxylic acid cycle

The TCA cycle produces reducing equivalents for oxidative phosphorylation and is a vital metabolic process in non-photosynthetic organisms which produce the bulk of their cellular ATP in mitochondria. In contrast mitochondrial respiration rates in nutrient replete phototrophic and mixotrophic conditions average approximately 10–15% of gross photosynthetic rates across many phyla of microalgae including chlorophytes like *C. reinhardtii* [64]. In fact, several genes exclusive to the TCA cycle have been reported as non-essential for the growth of photosynthetic organisms [65]. Consequently, the availability of an organic carbon source is not expected to have a significant impact on the activity of TCA genes. To verify the validity of the above hypothesis, the expression level of the TCA exclusive *FUM1* gene, which encodes the enzyme fumarate hydratase that catalyses the reversible hydration of fumarate to malate (Fig. 5A) was measured across all experimental conditions.

The addition of acetate had no impact on *FUM1* expression in cultures grown under white and red light (WA, WX and RA, RX; Fig. 5B). In fact, *FUM1* expression levels were statistically similar across all four conditions (WA, WX, RA, RX; Fig. 5B). This indicates, as expected, that there is no correlation between biomass growth (Table 2) and TCA cycle activity (assessed through the expression levels of *FUM1* in the present study) in the nutrient replete conditions considered herein. Wavelength selection on the other hand, had a statistically significant effect on the expression level of *FUM1* (Fig. 5B). Specifically, *FUM1* expression was significantly lower in phototrophic cultures grown under blue light (BA). Interestingly, in cultures grown under blue light (BA, BX; Fig. 5B) the addition of acetate in the media led to an increased average expression level for *FUM1*. The increased expression level under blue light corresponded to an increased biomass growth rate (BX, Table 2) indicating that the additional carbon might be channelled towards mitochondrial respiration and ATP synthesis [66]. The positive correlation between *FUM1* expression and biomass growth rate for cultures grown under blue light suggests that in the presence of a readily available carbon source cellular growth could rely on TCA cycle activity and heterotrophy.

3.4.2. Glyoxylate cycle

Algae can preferentially utilize acetate as a carbon source due to the availability of an abbreviated version of the TCA cycle, sharing five of the eight TCA cycle enzymes, known as the glyoxylate cycle. This enables them to bypass the two decarboxylation steps found in the TCA cycle and enables the biosynthesis of macromolecules from simple C2 carbon compounds [62,67]. The preferential use of the glyoxylate cycle...
in the presence of a C_2 organic acid has been recently investigated using a genome scale metabolic model of _C. reinhardtii_ metabolism under nutrient replete mixotrophic and phototrophic conditions \[68\]. Although qualitative in nature, the results suggested a substantially increased flux through the glyoxylate cycle in the presence of a C_2 organic acid. This theoretical model based approach was able to accurately predict the experimentally observed change in oxygen evolution rate between the two conditions \[68\]. In the present study, the expression of a glyoxylate cycle exclusive gene, _MAS1_, was measured across all experimental conditions. The _MAS1_ gene encodes malate synthase, an enzyme that catalyses the formation of malate (C_4) from glyoxylate (C_2) and acetyl-CoA (C_2\_3 – Fig. 5A).

Surprisingly, the presence or absence of acetate had a statistically significant effect on _MAS1_ gene expression levels only in cultures grown under blue light (BA, BX; Fig. 5C). The 1.5-fold upregulation (\(p < 0.01\)) of _MAS1_ in mixotrophic cultures grown under blue light (BX) did not result in an increased biomass growth rate (Table 2). In conjunction with the observed upregulation of the TCA exclusive _FUM1_ in mixotrophic growth conditions (BA, BX; Fig. 5C), these results seem to indicate that carbon derived from acetate can help supplement biomass growth rate in non-optimal light conditions. No significant change in _MAS1_ expression levels was detected between phototrophic and mixotrophic conditions for cultures grown under white and red light (WA, WX and RA, RX; Fig. 5C). This is in contrast to previous studies \[20,69\] where an upregulation of glyoxylate cycle genes was observed following the addition of acetate. One possible explanation is that _MAS1_ expression levels are not linked to flux through the glyoxylate cycle in non-growth inhibited, constantly illuminated cultures (WA, WX, RA, RX) due to regulation occurring primarily by enzyme phosphorylation \[70\]. In fact, no correlation between growth (Table 2) and _MAS1_ expression (Fig. 5C) was found for cultures grown under white and red (WA, WX and RA, RX) light in the present study. Finally, wavelength selection was found to have a significant effect on _MAS1_ expression levels (Fig. 5C), with cultures grown under red light having a higher average expression level (\(p < 0.05\)).

### 3.4.3. Fatty acid synthesis

Acetyl-CoA derived from assimilated acetate in mixotrophic cultures can be channelled towards fatty acid biosynthesis which is driven by the heterogeneous fatty acid synthase (FAS) enzyme complex in the chloroplast \[71\]. The fatty acids generated can increase the cell’s intracellular free fatty acid (FFA) pool or they can be incorporated into one of the many lipid classes produced by _C. reinhardtii_ \[72\]. A multi-omics study found that protein levels of enoyl-ACP reductase were reduced during nitrogen deprivation, alongside a transient decrease in all FAS complex related transcripts during the first 12–48 h \[21\]. However, in the nutrient replete conditions of this study, where highly differing growth rates were observed between conditions it would be interesting to follow the gene expression of FAS complex related transcripts as a preliminary indicator of changes in macromolecular composition at a cellular level and in the assimilation of acetate derived carbon. The gene _KAS2_ encodes 3-ketoacyl-ACP synthase (KAS), the third enzyme in the FAS complex, which adds two carbons per FAS-cycle to the growing acyl-ACP chain using malonyl-ACP as its substrate (Fig. 5A).

Trophic strategy selection had an impact on _KAS2_ expression level in cultures illuminated under white and red light (WA, WX and RA, RX;
growth rate (Table 2). On the other hand, there was no change in biomass growth rate observed between trophic strategies in cultures grown under red light (RA, RX; Fig. 5D). Meanwhile a statistically significant increase in KAS2 expression was observed in red light mixotrophic cultures (RX; Fig. 5D). One possible explanation could be that in cultures grown under red light with a smaller average cell size (Fig. 4) but otherwise comparable biomass growth rate (Table 2), the assimilated acetate in the form of acetyl-CoA is preferentially funnelled towards fatty acid production. This would lead to an increased production rate for membrane-lipids, necessary to support the shorter cell-cycle with more cell divisions per unit time for cells grown under red light (Fig. 4).

Previous studies have shown that the autophagous degradation of membrane lipids for TAG production under nitrogen starvation is less pronounced in mixotrophic C. reinhardtii cultures grown in white light [73] further hinting at an increased flux of acetyl-CoA towards fatty acid synthesis during mixotrophy.

The gene expression data discussed in the preceding sections is summarised in Table 2. Mixotrophic cultures grown under constant red light illumination had the highest average fold expression for all genes considered thus far. However, this did not translate directly into an increased biomass growth rate as could have been expected given the nature of the genes investigated. This indicates that despite similarities in the observed biomass growth rates across conditions considered herein (Table 2), the macromolecular composition of cells will change depending on the utilised trophic and illumination strategy.

3.5. Recombinant protein promoter genes

In recent years, a number of sophisticated genome editing technologies have been adapted to microalgae [74]. C. reinhardtii, often referred to as the model microalgae, has the most complete algal genome editing toolbox however genetic engineering techniques are being developed for other type of algae as well [75,76]. Recombinant protein expression in C. reinhardtii has been attempted by integration of the recombinant genes into either the chloroplast [77] or the nuclear genome [78]. Each approach has its own benefits and limitations, with no clear consensus on an optimal strategy due to a lack of bioreactor (or larger) scale studies. As algal genome editing technologies mature, process development for recombinant protein expression will have to explore candidate promoters and culture conditions that lead to optimal transcriptional activity. In order to understand the magnitude of the impact process conditions can exert on transcriptional activity, the expression of a series of genes with promoters and/or 5’/3’ UTR(s) that have been previously used to facilitate recombinant gene expression in C. reinhardtii (Table 1) was evaluated across all experimental conditions. Bearing in mind that transcription and translation do not necessarily correlate well, some high level conclusions can be drawn from the data presented below.

3.5.1. Ribulose bisphosphate carboxylase small chain (RBSC)

RBSC2 is routinely used as a constitutive promoter for nuclear transgene expression in tandem with HSP70A [79-81]. RBSC expression was upregulated in both phototrophic and mixotrophic cultures grown under red light illumination (RA, RX; Fig. 2A). Fig. 7 presents RBSC expression data for an additional time point in the late stationary phase of the culture. In agreement with the results of Fig. 2A, RBSC expression is upregulated significantly for cultures grown under red light (RA, RX; Fig. 7A). Interestingly, there is a large increase in RBSC expression during the stationary phase (136 h) for both mixotrophic and phototrophic cultures grown in red light. These results suggest that red light illumination would be preferable for recombinant protein synthesis when RBSC2 is used as a constitutive promoter.

3.5.2. Heat shock protein 70A (HSP70A)

HSP70A encodes a heat-shock protein, transcriptionally controlled through elevated temperatures and light [79]. It has been used as a transcriptional activator of other promoters, most commonly RBSC2 and recently RBSC2 with RBSC2 introns interspersed in the recombinant gene coding sequence [52]. In photoautotrophic cultures, a notable increase in expression was only observed during the stationary phase (136 h) of cultures grown in red light (Fig. 7B). HSP70A expression levels were higher in the stationary phase of mixotrophic cultures across all wavelengths with a notable 6-fold increase (p < 0.05) observed in cultures grown under blue light illumination (Fig. 7B).

3.5.3. Adenosine triphosphate synthase subunit alpha (atpA)

Assembly of chloroplastic ATP-synthase requires subunits encoded in both the nuclear and the plastid genomes [82]. The gene atpA is native to the plastome and encodes sub-unit alpha of the CF1 complex [83]. Its 5’UTR and promoter coding regions have been used to drive both nuclear [84-86] and plastid [87,88] gene expression. Cultures grown under white light illumination had the lowest levels of atpA expression across all conditions examined (Fig. 7). Interestingly, trophic strategy had a significant impact on atpA expression only in cultures grown under red light where a 5.5 fold upregulation was observed in mixotrophic cultures during the mid-exponential phase (16 h and 48 h).

These results confirm that culture time, trophic strategy and wavelength selection can all have a significant impact on the transcriptional activity of promoters and should be considered as critical process parameters during process development and optimisation.
The expression profiles of a total of 16 genes (Table 1) were monitored across C. reinhardtii cultures grown under two different trophic strategies and three different wavelengths. This enabled the identification of novel reference genes (psaD and ACX1) with significantly improved expression stability compared to commonly used reference genes, for the conditions explored herein. The analysis of the expression profiles of representative genes from key metabolic pathways revealed that trophic strategy and wavelength selection have an impact on some aspects of central carbon metabolism in algae. Specifically, wavelength selection was found to have an impact on photosynthetic efficiency and (as indicated by cell size distribution data) the cell cycle. Moreover, based on the set of gene expression profiles examined in the present study, assimilated acetate was found to be primarily channelled towards fatty acid synthesis, particularly in cultures grown under red light illumination. Finally, the expression profiles of three commonly used promoters for the expression of recombinant proteins were evaluated across all experimental conditions and revealed that culture time, trophic strategy and wavelength selection should be considered as critical process parameters during process development and optimisation. The evaluation of a panel of candidate reference genes under the diverse conditions examined herein highlighted the importance of establishing a priori a systematic workflow that facilitates reliable comparisons across culture conditions and will hopefully inform the experimental design of future studies.
