\textbf{ABSTRACT}

Rhizospheres are microecological zones at the interface of roots and soils. Interactions between bacteria and roots are critical for maintaining plant and soil health but are difficult to study because of constraints inherent in working with underground systems. We have developed an in-situ rhizosphere imaging system based on transparent soils and molecular probes that can be imaged using confocal microscopy. We observed spatial patterning of polysaccharides along roots and on cells deposited into the rhizosphere and also co-localised fluorescently tagged soil bacteria. These studies provide insight into the complex glycan landscape of rhizospheres and suggest a means by which root / rhizobacteria interactions can be non-disruptively studied.

The interface of roots and soil, the rhizosphere, is a microecological zone harbouring a rich diversity of microbes (the rhizobiome) (Daniel, 2005; Wagg et al., 2014). Interactions between the root and rhizobiome are complex, dynamic and important for plant health in relation to nutrient and water uptake, defence against pathogenic and herbivorous organisms, and root colonisation by arbuscular mycorrhizal fungi (Ferreira et al., 2020). Healthy soils are characterised by having diverse rhizobiomes, and diversity is known to be strongly influenced by molecules deposited by roots into the rhizosphere (rhizodeposits) (Richardson, 2001; Mendes et al., 2013; Olek-Lalzar et al., 2014; Tkacz and Poole, 2015; Jacoby and Kopriva, 2019). Metabolites such as hormones (e.g. strigalactone) and phenols (e.g. coumarins) have long been implicated in promoting favourable root-microbe interactions (Jacoby and Kopriva, 2019). The roles of complex polysaccharides in root-microbe interactions has received less attention, although they are abundant in the rhizobiome both as exuded mucilage, on the surface of epidermal cells and sloughed off border cells and as components of microbial biofilms. Evidence from other terrestrial and marine ecosystems demonstrates that polysaccharide complexity drives cognate microbial diversity via evolution of highly specialised carbohydrate active enzymes (CAZymes) that enable microbes to utilise glycan substrates (Flint et al., 2012; Bennke et al., 2016; Grondin et al., 2017; Lapèbie et al., 2019). There is also evidence that qualitative and quantitative variations in polysaccharide-rich root exudates and those that are surface bound have a major influence on soil microorganisms (Kuzyakov and Domanski, 2000; Dennis et al., 2010; Galloway et al., 2018; Jacoby and Kopriva, 2019). In some cases, glycans have been identified that are associated with colonisation by specific microbes, for example, galactans in potato root exudates and Pectobacterium atrosepticum (Koroney et al., 2016). Structurally complex proteoglycans (extensins and arabino-galactan-proteins) are abundant in exudates and appear to have roles in both plant growth promotion and defence (Ngueuma-Osa et al., 2013; Castilleux et al., 2019). However, a detailed understanding of the roles that glycans either in rhizodeposits or on root surfaces (rhizoglycans) play in maintaining rhizobiome diversity is lacking, partly because of the technical challenges associated with sampling and analysing glycans at the precise locations where these complex root-microbe interactions occur in this underground microecological zone.

Prior work by the authors and others using polysaccharide-directed monoclonal antibodies (mAbs) and carbohydrate binding modules (CBMs) has revealed how epitope distribution varies markedly along the root surface, with characteristic and consistent glycan labelling associated with the main body of the root, the root tip, root hairs and exudates including border cells (Willats et al., 2001; McCartney et al., 2016). These in vitro experiments show that root glycan patterning is complex and dynamic. However,
Fig. 1. A novel technology platform for an in-situ rhizosphere glycobiology. The transparent soil system is based on a thin glass chamber housing Nafion artificial soil particles in which seedlings grow. Bacteria, molecular probes and other components can be introduced via ports and the system washed with buffers. Using confocal and light sheet microscopy, rhizosphere polysaccharides, fluorescently tagged bacteria and Nafion particles are imaged in-situ.

Fig. 2. Imaging root associated polysaccharides using a transparent soil system. Lettuce seedling roots growing through Nafion soil particles (SP) were labelled with mAbs with specificity for xylogalacturonan (A), (1→4)-β-D-galactan (B) and (C) homogalacturonan (D) and (1→5)-α-L-arabinan (E). RT = root tip. SP = soil particle. Scale bars = 200µm.
they do not provide information on how this patterning changes over time with root growth and how glycan deposition may be influenced by interactions between roots and soil particles, and the effects of microbial degradation.

Specialised chambers of various kinds (rhizotrons) have been used for 125 years for observing roots in soil and for sampling material from degradation. Interactions between roots and soil particles, and the effects of microbial colonisation that combines a Nafion-based TSS with -particles in the TSS and allowed to migrate through and freely colonise the TSS (Fig. 3). We visualised GFP-tagged Escherichia coli colonies adhering to root hairs (Fig. 3A), and by inoculating with GFP-tagged Bacillus subtilis NRS1473 (Hobley et al., 2013) and simultaneously probing with mAb (LM15) that recognises xyloglucan (Marcus et al., 2008), we were able to co-localise B. subtilis and xyloglucan on root hairs (Fig. 3B). The observation that xyloglucan is abundant on root hairs and at the elongation zone is consistent with previous work on in vitro labelling studies (Freshour et al., 2003; Larson et al., 2014). The co-localisation with bacteria observed in this study is significant because it provides new insight into how interactions between root growth and soil properties contribute to the localisation of microbes with specialised capacity to utilise those glycans. We further explored associations between root polysaccharides and microbial colonisation by combining both GFP-tagged strains of soil bacteria and mAbs. Bacteria were inoculated onto 0.5 cm² filter paper and simultaneously labelled with the anti-xyloglucan mAb LM15 (red, Alexa594) revealing that this polysaccharide was abundant on the root hair surface; for 125 years for observing roots in soil and for sampling material from degradation.

Interactions between roots and soil particles, and the effects of microbial colonisation that combines a Nafion-based TSS with -particles in the TSS and allowed to migrate through and freely colonise the TSS (Fig. 3). We visualised GFP-tagged Escherichia coli colonies adhering to root hairs (Fig. 3A), and by inoculating with GFP-tagged Bacillus subtilis NRS1473 (Hobley et al., 2013) and simultaneously probing with mAb (LM15) that recognises xyloglucan (Marcus et al., 2008), we were able to co-localise B. subtilis and xyloglucan on root hairs (Fig. 3B). The observation that xyloglucan is abundant on root hairs and at the elongation zone is consistent with previous work on in vitro labelling studies (Freshour et al., 2003; Larson et al., 2014). The co-localisation with bacteria observed in this study may indicate that xyloglucan serves as a nutrient source at this location, thus creating a micro-ecological niche exploitable by microbes with the appropriate CAZymes to utilise xyloglucan.

using a Laser Scanning Confocal Microscopy (LSCM), and Light Sheet Microscopy (Yang et al., 2013). Using this system, it was possible to localise specific epitopes associated with living roots and the rhizosphere in the context of soil particles. We observed localisation of extensin, xylogalacturonan, (1 → 4)-β-D-galactan, homogalacturonan and (1 → 5)-α-L-arabinan on differing tissues around the root tip zone using the primary antibodies LM1 (Smallwood et al., 1995), LM8 (Willats et al., 2004), LMS (Jones et al., 1997), JIM5 (Knox et al., 1990; Clausen et al., 2003; Verhertbruggen et al., 2009) and LM6 (Willats et al., 1998) respectively. We also observed discrete labelling of specific tissues rich in (1 → 4)-β-D-galactan (LMS binding to border cells), xylogalacturonan (LMB binding to sloughed off tissue), and xyloglucan (LM15 particularly abundant on root hairs). Examples of these localisations are shown in Fig. 2. LSCM imaging revealed that soil porosity and particle geometry can significantly impact local deposition of polysaccharides. This was clearly demonstrated for xylogalacturonan and (1 → 4)-β-D-galactan (Fig. 2A and 2B and 2C respectively), both of which are associated with epidermal and border cells. Where roots grew between closely opposed soil particles, ‘pinch points’ were created that appeared to abrade cells from the root surface, thus creating massive local accumulations of cells and their associated glycans (Fig. 2A-2C). We also observed that some cells, cellular material and associated polysaccharide epitopes appeared to become ‘smearied’ onto soil particles, presumably as roots grew through soil pores. An example of this for homogalacturonan is shown in Fig. 2D. These observations are significant because they provide new insight into how interactions between root growth and soil properties contribute to glycan patterning in the rhizosphere, which is likely to in turn impact the localisation of microbes with specialised capacity to utilise those glycans.

Germinated 5-day old lettuce seedlings were placed at the top of the TSS chamber and roots grew into the Nafion matrix. Roots were blocked using 0.5% Bovine Serum Albumin (BSA) in phosphate buffered saline (PBS) for 30 min, prior to circulation of primary mAbs (diluted to 1:10 with PBS) for 1.5 hr. Both blocking buffer and mAbs were circulated through the chamber via the upper inlet and lower outlet using a peristaltic pump. Primary mAbs were washed out by flushing the system with PBS buffer. Fluorophore tagged secondary antibodies (anti-Rat Alexa Fluor® 488, diluted to 1:100 in PBS) were used to visualise primary mAb binding. The thin and transparent TSS chamber enabled direct non-disruptive in situ imaging of fluorescently labelled entities

**Fig. 3. Imaging of microbes and glycans.** (A) colonies of GFP-tagged E. coli 0157:H7 (EC, green punctate labelling) observed within the root hair (RH) matrix of a *Lactuca sativa* root; (B) GFP-tagged *B. subtilis* (BS, green punctate labelling) were inoculated into the TSS and also colonised *Lactuca sativa* root hairs. Roots were simultaneously labelled with the anti-xyloglucan mAb LM15 (red, Alexa594) revealing that this polysaccharide was abundant on the root hair surface; (C) as in (B) showing *B. subtilis* colonies (BS, green punctate labelling) located on the main root surface with xyloglucan labelling (mAb LM15, Alexa594) displayed in blue to contrast with Naphion soil particles. Scale bars, A = 50µm, B = 100µm, C = 200µm.
Our results clearly show that a significant amount of polysaccharide-rich material is retained on or near the root surface, despite the washing steps employed. It seems reasonable to speculate that the same may also be true to roots growing naturally in soils subject to rainwater. Nevertheless, it is likely that some polysaccharides are washed through the TSS and therefore were not observed, the system only provides partial insight onto glycan rhizodepositions. However, we envisage that the novel methodology described here can make a significant contribution to our understanding of the roles that glycans play in establishing and maintaining rhizobiome diversity. This in turn may help us identify novel means to fine tune rhizobioes to enhance plant health and crop performance.
