Abstract. The asymptotic structure of outflows from rotating magnetized objects confined by a uniform external pressure is calculated. The flow is assumed to be perfect MHD, polytropic, axisymmetric and stationary. The well known associated first integrals together with the confining external pressure, which is taken to be independent of the distance to the source, determine the asymptotic structure. The integrals are provided by solving the flow physics for the base within the framework of the model developed in Paper I (Lery et al. 1998), which assumes conical geometry below the fast mode surface, and ensures the Alfvén regularity condition. Far from the source, the outflow collimate cylindrically. Slow (i.e. with small rotation parameter \( \omega \)) rigid rotators give rise to diffuse electric current distribution in the asymptotic region. They are dominated by gas pressure. Fast rigid rotators have a core-envelope structure in which a current carrying core is surrounded by an essentially current free region where the azimuthal magnetic field dominates. The total asymptotic poloidal current carried away decreases steadily with the external pressure. A sizeable finite current remains present for fast rotators even at exceedingly small, but still finite, pressure.

1. Introduction

Jets from young stellar objects (YSO) and active galactic nuclei (AGN) are most likely launched magnetically. Various approaches have been used to describe the stationary configuration of magnetically collimating winds governed by the Grad-Shafranov equation (e.g. Lery et al. 1998 hereafter Paper I, and references therein). Magnetized ro-
Pudritz 1992, at the disk-magnetosphere boundary (“X-winds”, Shu et al. 1988, 1993, 1996) or directly from the star itself by combined pressure and magneto-centrifugal forces (“Stellar wind”, Weber & Davis 1967, MacGregor 1996 and reference therein). In order to make the system of equation more tractable angular self-similarity has been often employed for non rotating magnetospheres (Tsinganos & Sauty 1992), and outflows from spherical rotating objects (Sauty & Tsinganos 1994, Trussoni et al. 1997), Tsinganos et Trussoni 1991). Cylindrical self-similarity has also been used for magnetized jets (Chan & Henriksen 1982), and spherical self-similarity for disk winds (Blandford & Payne 1982, Henriksen & Valls-Gabaud 1994, Fiege & Henriksen 1996, Contopoulos & Lovelace 1994, Ferreira & Pelletier 1995, Ferreira 1997, Ostriker 1997, Lery et al. 1999). However this assumption presents boundary condition restrictions. Several numerical simulations, such as Ouyed & Pudritz 1997, have been made in order to understand the formation of magnetized jets from keplerian discs, but due to computational limitations only a few cases have been studied. One should also note that pure hydrodynamic collimation could be effective at producing jets (Frank & Mellema 1996). High velocity outflows from YSO and AGN are observed to be highly collimated. Heyvaerts & Norman 1989 have discussed how streamlines asymptotically develop in winds with different properties without considering confinement by any external medium (see also Heyvaerts 1996). They have shown that winds which carry a non-vanishing Poynting flux and poloidal current to infinity must contain a cylindrically collimated core, whereas other winds focus parabolically. Li et al. 1992 showed how the formation of weakly collimated, conical flows depends on the shape of the poloidal field near the Alfvén surface. The transition from weakly collimated flows to highly collimated jets has been also studied by Sauty & Tsinganos 1994.
based on the assumption that the magnetic surfaces possess a shape which is a priori known inside the fast critical surface. As a first approximation magnetic surfaces were taken to be cones. Unlike the Weber-Davis type models, the balance of forces perpendicular to the magnetic surfaces is taken into account on the Alfvénic surface through the Alfvén regularity condition. This, together with the criticality conditions determine the three unknown constants of the motion, that are conserved along magnetic surfaces \( a \), namely the specific energy \( E(a) \), the specific angular momentum \( L(a) \) and the mass to magnetic flux ratio \( \alpha(a) \). Once these first integrals are determined, the asymptotic cylindrically collimated flow is uniquely determined. The solutions are parameterized by the angular velocity of the magnetic field lines \( \Omega(a) \), the specific entropy at the base \( Q(a) \) and by the mass flux to magnetic flux ratio on the polar axis \( \alpha_0 \). According to the rotation parameter \( \omega = \frac{\Omega r}{a^2} \) the objects can be classified as slow \( (\omega << 1) \), fast \( ((\frac{3}{2})^{3/2} - \omega << 1) \) or intermediate (other values of \( \omega \) ranging between 0 and \( (\frac{3}{2})^{3/2} \)) rotators. Critical surfaces are nearly spherical for slow rotators, but become strongly distorted for rapid rotators, giving rise to important gradients of density and velocity that should consequently affect asymptotic quantities. This simplified model makes it possible to investigate the structure of outflows far from the magnetized rotator source without the need for self-similar assumptions. The price to pay for that is that the model does not give an exact, but only an approximate, solution because the transfield equation is not solved everywhere, but only at a few special places.

How outflows behave in the asymptotic region constitutes the subject of the study of this paper which also focuses on the study of the asymptotic electric current and addresses the question of the asymptotic collimation of the different classes of rotators found in Paper I. In this paper, we present a model where the collimated jet is assumed to be in pressure equilibrium with an external medium whose properties are independent of the distance to the source. The question of the asymptotic electric current is a major concern for jets that will be investigated.

We structure our paper as follows: In \( \S 2 \), we present the equations governing the asymptotic equilibrium, and their boundary conditions. Solutions and parameter studies are presented in \( \S 3 \). We derive analytical and numerical solutions for the asymptotic electric current in \( \S 4 \). Finally, in \( \S 5 \), we discuss the implications of our analysis and we summarize our results in \( \S 6 \).

matter to magnetic flux $\alpha(a)$, expressed through the density at the Alfvén point $\rho A(a)$, are also conserved along the flux surfaces and follow from the regularity of the solution at the Alfvénic and fast and slow magnetosonic surface.

2.2. The Intermediate Zone

The MHD flow in regions causally disconnected from the base region has no back-reaction on its properties in this region. It is known that this causally disconnected region starts at the so-called fast limiting characteristic (Tsinganos et al. [1997]), which is usually situated downstream from the fast magnetosonic surface. The flow in the causally disconnected region has no influence on the values assumed by the three first integrals which are not a-priori known. The flow between the fast mode critical surface and the fast mode limiting separatrix would have some influence on their determination if the shape of magnetic surfaces between the source object and the fast limiting separatrix were self-consistently calculated. Moreover we can consider $r$ to be larger than $r A$. Using the assumptions $r \gg r A$ and $\rho A \gg \rho$, the last two terms of the Eq. (6) become

$$\frac{1}{2} \left( \frac{\alpha \, da}{\rho \, dr} \right)^2 = E(a) - G(r, z) - \frac{\gamma}{\gamma - 1} Q \rho^{\gamma - 1} - \frac{L - r^2 \Omega}{\rho A - \rho}$$

$$+ \frac{1}{2} \left( \frac{L + \rho \, L - r^2 \Omega}{\rho A - \rho} \right)^2.$$ \hspace{1cm} (1)

This equation can be simplified in the asymptotic region, i.e. $z$ going to $\infty$, so that gravity becomes negligible. In the cylindrical case, $\nabla a$ is replaced by $\partial a/\partial z$. Since we are far from the Alfvén surface in the asymptotic region, the density of the flow $\rho$ must be smaller than the Alfvén density $\rho A$. Moreover we can consider $r$ to be larger that $r A$. The lack of complete self-consistency of our model is therefore mainly contained in our assumption of base conical geometry. The fact that the shape of surfaces is not calculated downstream from the fast surface in regions were field curvature is still present, i.e. where poloidal field lines are dashed in Fig. [2], does not add any supplementary inaccuracy.

The shape of the magnetic surfaces shown in Fig. [2] are similar, to some extent, to shapes obtained by some previous studies already performed for a self-consistent calculation of the shape of the poloidal field lines. Trussoni et al. (1997) have prescribed similar types of the magnetic surfaces and then integrated the MHD equations from the base all the way to infinity. Such case corresponds to meridionally self-similar MHD outflows with a non-constant polytropic index $\gamma$. Sauty and Tsinganos (1994) have also calculated the shape of magnetic field lines by deducing them and integrating the MHD equations from the base to large distances.

2.3. The Asymptotic Structure

The asymptotic structure of the flow is determined by solving exactly the transfield equation. However, in the present simplified and fixed base geometry, these first integrals are entirely determined from sub-fast surface regions and there is no need, for their determination, nor for that of the asymptotic structure, to calculate the geometry of magnetic surfaces in the intermediate region between the fast critical surface and the fast mode limiting separatrix. The latter is anyway presumably located not much further away from it and we do not expect large geometrical changes as compared to the base region. The lack of complete self-consistency of our model is therefore mainly contained in our assumption of base conical geometry. The fact that the shape of surfaces is not calculated downstream from the fast surface in regions were field curvature is still present, i.e. where poloidal field lines are dashed in Fig. [2], does not add any supplementary inaccuracy.

The Bernoulli Equation Let us define $L$ as the total angular momentum, $\rho A$ as the mass density at the Alfvén critical point and $G(r, z)$ as the gravitational potential. The Bernoulli equation can be given by

$$\frac{1}{2} \left( \frac{\alpha \, da}{\rho \, dr} \right)^2 = E(a) - G(r, z) - \frac{\gamma}{\gamma - 1} Q \rho^{\gamma - 1}$$

$$+ \frac{L - r^2 \Omega}{\rho A - \rho} - \frac{1}{2} \left( \frac{L + \rho \, L - r^2 \Omega}{\rho A - \rho} \right)^2.$$ \hspace{1cm} (1)

This equation can be simplified in the asymptotic region, i.e. $z$ going to $\infty$, so that gravity becomes negligible. In the cylindrical case, $\nabla a$ is replaced by $\partial a/\partial z$. Since we are far from the Alfvén surface in the asymptotic region, the density of the flow $\rho$ must be smaller than the Alfvén density $\rho A$. Moreover we can consider $r$ to be larger that $r A$. The last two terms in brackets are negligible w.r.t. unity. Moreover when $z$ tends to infinity, $\rho r^2$ is bounded. Therefore the parenthesis of the first term inside the brackets is also bounded, and, if $r$ were to approach infinity, the first term in bracket would also be negligible with respect to unity. We assume that, even though $r$ approaches a finite limit, $(r A/r)$ becomes asymptotically small enough for this first term in bracket to also become negligible. Thus the last two terms of the Bernoulli equation can be approximated at infinity by $-\rho \Omega^2 r^2/\rho A$. Hence, the Bernoulli equation becomes

$$\frac{1}{2} \left( \frac{\alpha \, da}{\rho \, dr} \right)^2 = E - \frac{\gamma}{(\gamma - 1)} Q \rho^{(\gamma - 1)} - \frac{\Omega^2 r^2 \rho}{\mu_0 \alpha^2}.$$ \hspace{1cm} (4)

The Transfield Equation The force balance perpendicular to the field can be written in cylindrical coordinates as

$$\frac{\partial \theta}{\partial r} \left( \frac{1}{r} \frac{\partial \phi}{\partial \theta} + \frac{1}{\alpha} \frac{\partial \alpha}{\partial \theta} \right) - \frac{1}{\rho \mu_0 \alpha} \left( \frac{\partial}{\partial r} \frac{1}{\alpha} \frac{\partial \alpha}{\partial r} + \frac{1}{\alpha} \frac{\partial \alpha}{\partial \theta} \right)$$

$$= E' - \frac{\Omega^2 \rho^{(\gamma - 1)}}{\gamma (\gamma - 1)} \frac{\mu_0 \alpha^2}{r^2} \frac{L - r^2 \Omega}{(\mu_0 \alpha^2 - p)^2}$$

$$- \frac{\rho}{\mu_0 \alpha^2} \left( L' - r \Omega r^2 \Omega \right) \frac{L - r^2 \Omega}{(\mu_0 \alpha^2 - p)^2} - \frac{\mathcal{E}'}{r^2}.$$ \hspace{1cm} (5)

Primes denote derivatives with respect to $a$, i.e. $E' = dE/da$. Similarly using the same asymptotic assumptions in the transfield equation, the centrifugal force $\rho \Omega^2 r/\mu_0 \alpha^2$ can be neglected with respect to “loop stress” $B^2/\mu_0 \rho$, since
Hence due to the simplifications, several force densities vanish in the one-dimensional form of the transfield equation that is then given by

\[
\frac{1}{2} \frac{d}{da} \left( \frac{\alpha}{\rho r \, dr} \right)^2 = E' - \frac{Q' \rho^{-1}}{\gamma - 1} + \frac{\rho r^2 \Omega^2}{\mu_0 \alpha^2} \left( \frac{\alpha'}{\alpha} - \frac{\Omega'}{\Omega} \right). \tag{7}
\]

Subtracting the transfield equation (7) from the derivative with respect to \( a \) of the Bernoulli equation (8), one can simplify the transfield equation that becomes

\[
\frac{r^2}{2} \frac{d}{da} (Q \rho^\gamma) + \frac{1}{2} \frac{d}{da} \left( \frac{\Omega^2 r^4 \rho^2}{\mu_0 \alpha^2} \right) = 0. \tag{8}
\]

Thus Eqs. (7) and (8) describe the asymptotic equilibrium structure of a magnetized jet with the present assumptions. To study the equilibrium of this jet taking into account an external ambient pressure, one needs to specify the relevant boundary condition at the jet’s edge.

**The Cylindrical Collimation** It is possible to show that the asymptotic problem with non-vanishing external pressure does not accept solutions where \( r \) goes to infinity on any magnetic field line. Indeed, if so, \( \frac{dr}{dz} \) would vanish at the edge of the jet. As a consequence \( B_p = \frac{1}{\gamma - 1} \frac{dz}{dr} \) would go to zero at the outer edge and the toroidal part of the magnetic field would asymptotically reduce to

\[
B_\phi = \mu_0 \alpha \frac{\rho}{\rho_A - \rho} \frac{L - r^2 \Omega}{r} \approx - \frac{\Omega}{\rho} \frac{r^2}{\alpha} \frac{\rho_A}{r}. \tag{9}
\]

If \( \rho r^2 \) were to diverge at the edge, the Bernoulli equation (8) would be violated, since the left hand side term is always positive, and the ninth term that is negative and the largest one in absolute value could not be balanced by other terms. It would also be so if the Alfvén radius were to become infinite. This proves that \( B_\phi \) and \( B_p \) should vanish if \( r \) were to approach infinity. If so, the boundary condition reduces to \( P_{\text{ext}} = P_{\text{gas}} = \frac{Q \rho_0^\gamma}{2} \). The density at the outer edge \( \rho_0 \) would then be finite, and \( \rho r^2 \) would diverge which violates the Bernoulli equation as shown above. This proves that the confining pressure limits the jet to a finite radius as \( z \to \infty \) and therefore ensure an asymptotically cylindrical structure.

**An Upper Limit for the Axial Density** Let us see now that the physics of the flow in the inner region close to the source constrains the maximum value of the asymptotic mass density on the polar axis, \( \rho_0 \), and therefore also the total mass flux for a given magnetic flux. Indeed, on the axis the Bernoulli equation reduces to

\[
(v_0^2/2) = E - \frac{\gamma Q \rho_0^{\gamma-1}}{\gamma - 1}, \tag{10}
\]

which yields an upper limit to the axial density (the limit corresponding to a vanishing asymptotic poloidal velocity).

In the inner region of the flow close to the source the energy has been calculated (see paper I). For slow rotators (that corresponds to a rotation parameter \( \omega \ll 1 \) energy is given by \( E = A^2/2\mu_0^2 \alpha^2 R_A^4 \), with the Alfvén spherical radius equal to \( R_A = (C_1 \mu_0 A^2/2)^{1/(2\sqrt{2}+4)} \), where \( C_1 \) is the constant of integration of the transfield equation that has been defined analytically in Paper I (Eq. (75)) only as a function of the input parameters. Combining the two last equations with Eq. (11), the maximum density becomes in this case

\[
\rho_{0,\text{max}} = \left( \frac{\gamma - 1}{\gamma - 2} \frac{\alpha A^2}{\gamma} \frac{4}{\mu_0^2 \alpha^2 Q} \left( \frac{2}{C_1 \mu_0 A^2} \right)^{2/(\gamma + 2)} \right) \frac{\rho_A}{\sqrt{2}+2}. \tag{12}
\]

In the vanishing rotation case, it is then possible to find an analytical definition of the maximum density on the axis in the asymptotic region allowed by the input parameters defining the emitting source properties. This also shows that the slow rotator limiting density essentially depends on the specific entropy \( Q \). For fast rotators and using Eq. (99) of Paper I that gives energy, the limiting mass density becomes

\[
\rho_{0,\text{max}} = \left( \frac{\gamma - 1}{\gamma - 2} \frac{\alpha A^2}{\gamma} \frac{4}{\mu_0^2 \alpha^2 Q} \left( \frac{2}{C_1 \mu_0 A^2} \right)^{2/(\gamma + 2)} \right) \frac{\rho_A}{\sqrt{2}+2}. \tag{13}
\]

This limit now depends on the entropy, but also on angular velocity and mass to magnetic flux ratio. The latter parameter is related to mass loss rate on the axis and therefore determine the axial value of density at the Alfvén point. Then an increase of \( \alpha_0 \) naturally reduces this limit. Thus, once given the properties of the source in our model \( (Q(a), \Omega(a), \alpha_0) \), the asymptotic axial density possesses an upper limit.

**The Boundary Condition** We further assume the flow to be in pressure equilibrium with an external medium whose pressure is constant. Equilibrium at the jet boundary is expressed by

\[
P_{\text{ext}} = Q \rho^\gamma + (B_\phi^2 + B_p^2)/(2\mu_0), \tag{14}
\]

with the magnetic contributions

\[
\frac{B_\phi^2}{2\mu_0} = \frac{\rho^2 \gamma^2 \Omega^2}{2\rho_A}, \tag{15}
\]

\[
\frac{B_p^2}{2\mu_0} = \frac{\rho^2}{\rho_A} \left( E - \frac{\gamma}{\gamma - 1} Q \rho^{\gamma-1} - \frac{\Omega^2 \rho^2}{\rho_A} \right). \tag{16}
\]

It has been used that at the outer boundary \( \rho \ll \rho_A \) and \( r >> r_A \). The pressure of the external medium may have a thermal and a magnetic contribution, too. In the case of a finite external pressure the jet radius remains finite.

Thus the asymptotic forms of the transfield and the Bernoulli equations that are the ultimate expressions of the asymptotic problem can be written as

\[
\frac{1}{2} \frac{d}{da} \left( \frac{\alpha}{\rho r \, dr} \right)^2 = 0, \tag{17}
\]

\[
\frac{r^2}{2} \frac{d}{da} (Q \rho^\gamma) = 0. \tag{18}
\]
three first integrals of the motion \(E(a), L(a)\) and \(\alpha(a)\) are obtained from the inner part of the flow (Paper I). At infinity the only free parameter is the external pressure \(P_{\text{ext}}\).

3. Numerical Analysis

3.1. Numerical Procedure

For the numerical calculations, the Bernoulli and the transfield equations have been reformulated as two ODEs for the radial position, \(r\), and the density, \(\rho\), as a function of the flux surfaces \(a\). The Bernoulli equation can be written as

\[
\frac{dr}{da} = \frac{\alpha}{\rho r \sqrt{\frac{3}{2} E - \frac{\gamma - 1}{\gamma - 1} Q \rho^{\gamma - 1} - \frac{\Omega^2}{\mu_0 \alpha^2}}} \tag{17}
\]

and the transfield equation can be written as

\[
\left(\mu_0 \gamma Q \rho^{\gamma - 2} + \frac{r^2 \Omega^2}{\mu_0 \alpha^2}\right) \frac{1}{\rho} \frac{dp}{da} + \left(\frac{2r \Omega^2}{\mu_0 \alpha^2}\right) \frac{dr}{da} = \frac{r^2 \Omega^2}{\mu_0 \alpha^2} \frac{da}{da} - \mu_0 \rho^{\gamma - 3} \frac{dQ}{da} - \frac{r^2 \Omega^2}{\mu_0 \alpha^2} \frac{d\Omega}{da}. \tag{18}
\]

These two equations can now be written symbolically as

\[
\frac{dr}{da} = f_r(r, \rho, E, Q, \alpha, ...), \tag{19}
\]

\[
\frac{dp}{da} = f_p(r, \rho, E, Q, \alpha, ...), \tag{20}
\]

where \(f_r\) is the r.h.s. of Eq. (17) and \(f_p\) has a more complex form that can be easily derived from Eqs. (18) and (17). We use a standard initial condition integrator for stiff systems of first order ODEs. We prescribe the axial density rather than the external pressure, which is ultimately deduced from the solution. As in paper I, dimensionless quantities \(\bar{\Omega}, \bar{\alpha}_0\) and \(\bar{Q}\) will respectively be used for \(\Omega, \alpha_0\) and \(Q\) in order to simplify numerical investigations. The reference units (in CGS) are \(\rho_{\text{ref}} = 70 \text{p.cm}^{-3}\), \(r_{\text{ref}} = 10^{15} \text{cm}, v_{\text{ref}} = 10^7 \text{cm.s}^{-1}\).

We will first consider the case of magnetized winds originating from objects with constant rotation and entropy. The effect of the four parameters is studied in the next subsections, followed by a specific application to the TTauri star BP Tau.

3.2. Variations of the Rotation

First we study the effect of the dimensionless angular velocity, \(\bar{\Omega}(a) = \Omega / \Omega_0\) of the central object. The other parameters remain constant. As in paper I, we find that the variations of the angular velocity have major effects on solutions as can be seen on Fig. 2 that shows the components of the magnetic field, the density and the poloidal velocity. As in paper I, we find that the velocity, \(\bar{\Omega}(a)\) variations remain within a factor of two. In the very fast rotator limit the density falls off dramatically in the envelope. In particular the poloidal velocity is highest in the envelope, though variations remain within a factor of two. In the very fast rotator limit the density falls off dramatically in the envelope where the gas pressure becomes negligible compared to the magnetic pressure. This is clearly shown in Fig. 3 where the total pressure is represented with magnetic and gas pressures. For slow rotators, the gas pressure dominates everywhere in the outflow, while for fast rotators the magnetic pressure dominates in the envelope. In the latter case, most of the outer pressure at the outer edge is supported by magnetic field and not by gas pressure.

In Fig. 5, the toroidal field increases nearly linearly, while it possesses a maximum within the jet for fast rotators. We find that \(B_\phi \propto 1/r\) while \(B_p \propto 1/r^2\). The two solutions respectively correspond to a diffuse current with nearly constant current density, and to a centrally peaked current, surrounded by a current-free envelope. A similar behavior has been discussed by Appl & Camenzind (1993) for relativistic jets, according to which the jet configurations had been referred to as diffuse and sharp pinch. Important variations with respect to rotation can also be seen in the other physical quantities. In particular the poloidal velocity is highest in the envelope, though variations remain within a factor of two. In the very fast rotator limit the density falls off dramatically in the envelope where the gas pressure becomes negligible compared to the magnetic pressure. This is clearly shown in Fig. 6, which is the total pressure is represented with magnetic and gas pressures. For slow rotators, the gas pressure dominates everywhere in the outflow, while for fast rotators the magnetic pressure dominates in the envelope. In the latter case, most of the outer pressure at the outer edge is supported by magnetic field and not by gas pressure.
Fig. 3. Rotational Effects: Comparison of pressure profiles for slow, fast and very fast rotators. Total, magnetic ($P_{\text{mag}}$) and gas ($P_{\text{gas}}$) pressure respectively correspond to solid, dashed and long dashed lines. The rotation parameter $\omega$ is equal to 0.4, 1.3 and 1.8 top to bottom respectively.

Fig. 4. Rotational Effects: Plot of the mass to magnetic flux ratio $\bar{\alpha}$ with respect to the relative magnetic flux $\alpha$. Heavy solid line correspond to slow rotators, and heavy dashed line to outflows with large $\bar{\alpha}$. All the other parameters and boundary conditions are kept the same.

3.3. Mass Loss Rate Effects

Another potentially observable quantity is the mass loss rate particularly interesting since it can be evaluated from observations. The parameter related to the mass loss rate is $\bar{\alpha}_0$. We have computed solutions for different $\bar{\alpha}_0$’s, keeping other parameters unchanged. The results are plotted in Fig. 5 where the poloidal components of the velocity $v_p$ and the magnetic field $B_p$ are represented as functions of the relative radius. The input values are $\bar{\alpha}_0 = 0.7, 0.8, 1, 1.4, 1.8, 2.6$, $\bar{\Omega} = 5$ and $\bar{Q} = 2.5$. From this figure we can infer that the maximum momentum is situated in the axial part, especially for fast rotators. Therefore the central part of the jet will propagate more easily in the ambient medium than the external part.

The profile of poloidal velocity depends sensitively on $\bar{\alpha}_0$ as well as the core radius that reduces as $\bar{\alpha}_0$ increases. As found in Paper I for the inner conical region, it appears that an increase in mass loss rate has a similar effect to a decrease of the rotation rate.

3.4. Thermal Effects

In this subsection we study the dependence of the outflow properties on specific entropy $Q_*$ on the stellar surface and polytropic index $\gamma$. The other parameters are given by $\bar{\Omega} = \Omega_* = 5$, $\bar{\alpha}_0 = 2.1$ and $\rho_0 = 10^{-5}$. Fig. 6 shows the poloidal velocity $v_p$ and the rotation parameter $\omega$ calculated at the outer edge of the flow as functions of the specific entropy $\bar{Q}$. The whole range in $\omega$ can be covered by only varying $\bar{Q}$. Smaller specific entropies correspond to larger $\omega$. For

Fig. 5. Mass Loss Rate Effects: Plots of poloidal components of velocity $v_p$ (left panel) and magnetic field $B_p$ (right panel) for various values of the mass to magnetic flux ratio on the axis $\bar{\alpha}_0$. Heavy solid line correspond to small mass loss rates and heavy dashed line to large ones. ($\bar{\alpha}_0 = 0.7, 0.8, 1, 1.4, 1.8, 2.6$, $\bar{\Omega} = 5$ and $\bar{Q} = 2.5$)
given \( \bar{\Omega} \) and \( \bar{\alpha}_0 \) the poloidal velocity presents a minimum when the rotation parameter \( \omega \) is almost equal to unity which corresponds to the intermediate class of rotators. Slow rotators are then accelerated by an increase of the heating, but not fast rotators. It has also been found that a change in specific entropy does not affect the azimuthal to poloidal magnetic field ratio but just produces an increase of magnitudes.

It has been found that the velocity can change by several orders of magnitude, between the adiabatic and isothermal flow, which are the narrower under the same conditions. In Fig. 6, the combined effects of \( \bar{Q} \) and \( \gamma \) are represented. The rotation parameter \( \omega \) is plotted with respect to \( \gamma \) for various values of \( \bar{Q} \). Two different classes of solutions can be distinguished, solutions for which \( \omega \) start at small values for \( \gamma = 1 \) and then decrease and solutions which have large \( \omega \) at \( \gamma = 1 \) and then increase. Thus the value of the specific entropy discriminates between fast and slow rotators while larger \( \gamma \)'s just tighten this distinction.

3.5. An Example: BP Tau

We now apply the jet model to the TTauri star BP Tau by using its properties, given by Bertout et al. (1988), which are \( \dot{M}_\ast = 2 \times 10^{-7} M_\odot \text{yr}^{-1}, \ M_\ast = 0.8 M_\odot, \ R_\ast = 3 R_\odot, \)

of the dimensionless reference values mentioned in section 3.1 \( \bar{Q} = 0.05, \ \bar{\Omega} = 1.8, \ \bar{\alpha}_0 = 0.1 \) and a relative central density of \( 10^{-4} \). These parameters allow to

![Fig. 6.](image-url)  
**Fig. 6.** Thermal Effects: Poloidal velocity \( v_p \) (upper panel) and rotation parameter \( \omega \) (lower panel) are plotted for \( \bar{Q} \) varying from 1.2 to 3.5 given at the boundary of the outflow. \( \omega \) varies from 0 to its maximum value. \( \bar{\Omega} = \Omega = 5, \bar{\alpha}_0 = 2.1 \) and \( \rho_0 = 10^{-5} \).

![Fig. 7.](image-url)  
**Fig. 7.** Thermal Effects: The rotation parameter \( \omega \) given at the outer boundary as a function of \( \gamma \) for different values of \( \bar{Q} \) (from 1 to 3.5) The smallest values of \( \bar{Q} \) (represented with solid lines) increase and reach the largest value of \( \omega \), while larger value of \( \bar{Q} \) (dashed lines) decrease and correspond to smaller values of \( \omega \).

![Fig. 8.](image-url)  
**Fig. 8.** Model for the jet of a TTauri star, BP Tau with \( \bar{\Omega} = 1.8, \bar{\alpha}_0 = 0.1, \bar{Q} = 0.05 \) and a relative central density of \( 10^{-4} \) (\( \omega = 1.41 \)). Upper panels correspond to the magnetic field (left) and the velocity components (right).
compute the dimensionless rotation parameter $\omega$ which is found to be 1.41 on the equator, and corresponds to the case of a fast rotator. Magnetic field and velocity components, density and gas pressure in the flow are plotted for BP Tau in Fig. 5 together with the magnetic flux represented as a function of the relative radius. The reference units (in CGS) are $\rho_{\text{ref}} = 70 \, \text{p/cm}^3$, $r_{\text{ref}} = 10^{15} \, \text{cm}$, $v_{\text{ref}} = 10^7 \, \text{cm/s}$.

The azimuthal component of the magnetic field dominates the poloidal part in the envelope. The poloidal velocity does not show strong variations across the jet, and the azimuthal velocity $v_\phi$ is one order of magnitude smaller than the poloidal component. The axial region is the densest and slowest part of the asymptotic flow. This dense core region is a fraction of the full jet with a minimum of 0.5 for the fastest case. This corresponds to a central core of the order of $5 \times 10^{14} \, \text{cm}$. Even if the fastest part is the outer one the maximum momentum is located around the polar axis. Hence even if the relative velocity is smaller close to the axis the central region of the flow will propagate faster in the ambient medium. It also is found that, only in the central part of the asymptotic outflow, does the kinetic energy flux dominate over Poynting flux. Thus a large part of the magnetic energy has not been transferred to the kinetic energy in the case of constant rotation.

3.6. Non-constant $\Omega$ and $Q$

The profiles of the differential angular velocities, that we use (See Paper I), are defined as follows: $\Omega_0$ corresponds to a constant rotation rate across the flow, $\Omega_1$ is a profile varying from $\Omega_0$ to zero with a step-like transition, the same for $\Omega_3$ but more smoothly, $\Omega_2$ and $\Omega_5$ vary from $\Omega_0$ to $\Omega_0/2$ and $1.5 \times \Omega_0$ respectively and finally $\Omega_4$ follows the differential rotation of a Solar-type star. The profiles of specific entropies are as follows: $Q_0$ is constant across the flow, $Q_1$ varies from $Q_0$ to $Q_0/2$ and $Q_2$ varies from $Q_0$ to zero like $Q_1$ but more smoothly in the latter case.

A number of well-collimated outflows are observed to have larger poloidal velocities near the polar axis, and lower velocities at the edge of the flow. This motivated us to use a profile of type $\Omega_2$ that could reproduce such behaviors. Fig. 6 represents the total pressure for such differential rotators with respect to the relative radius for a set of central values of the angular velocity. Similarly to rigid rotators, the pressure globally decreases from the axis to the outer edge, though the gradient of rotation causes a second peak of pressure to appear. The latter could correspond to a denser, slower and wider outflow surrounding the central fast jet. For slow and intermediate rotators, the inner pressure can be of order of the pressure at boundary of the outflow and the outer part can be as dense and slow as the axial region. A peak of poloidal velocity does itself embedded in a slower outer part. Differential rotators can then produce jets with a narrow central part with large momentum surrounded by a larger outflow with smaller momentum, as are jet surrounded by a molecular flow.

It is also found that some outflows like rigid rotators have smaller axial velocities than at the outer edge or present on the contrary a very fast component which corresponds to large gradients of the angular velocity. Differential entropies can also cause such inverted asymptotic solutions though with less amplitude in the variation of the poloidal velocity.

Variations of the entropy profile bring an interesting feature. We have shown previously that magnetic pressure dominates at the outer edge for fast rotators while gas pressure dominates for slow rotators. In fact, variations of the specific entropy enhances this difference as shown in Fig. 10 where the pressures are plotted with respect to the relative radius. The total pressure does not change much as compared to the case of constant entropy while the gas to magnetic pressure ratio $\beta$ decreases. Therefore $\beta$ can become quite low in some regions of the jet. This can have important consequences on the propagation of the jet and on the role of ambipolar diffusion (Frank et al. 1999) in the dynamics of large scale YSO jets and outflows.

4. The Asymptotic Electric Current

Heyvaerts and Norman (1989) have shown that the asymptotic shape of steady axisymmetric magnetized un-
form confining external pressure causes the flow to asymptote to a cylindrical shape. The aim of this section is to study the variation of the poloidal electric current w.r.t. the confining pressure.

The physical poloidal current through a circle centered on the axis of symmetry and flowing between this axis and a magnetic surface a is given by \( I_{\text{phys}}(a) = 2\pi r B_a / \rho_0 \). The related, usually positive quantity \( I = -I_{\text{phys}} / 2\pi r \), which we will still refer to as the "poloidal electric current" therefore contains entirely equivalent information. The value of the flux surface index, \( a \), at the equator corresponds to the external pressure. It has been found convenient to first consider constant \( \Omega(a) \) and \( Q(a) \) to be constant, the transfield equation similarly reduces to

\[
\ddot{y} = -y \left( \frac{2\omega^2 \dot{x}}{\gamma (\gamma - 1) \beta y^{\gamma - 2} + 2\omega^2 x} \right).
\]

This equation integrates as

\[
\beta y^{\gamma - 1} + 2\omega^2 xy = C
\]

where \( C \) is an integration constant which can be related to the axial density \( y(x = 0) = y_0 \) as

\[
C = \beta y_b^{\gamma - 1}
\]

Using Eq. \( (26) \), Eq. \( (22) \) becomes

\[
I = \frac{A}{2r_A \mu_0 \omega} \beta \left( y_0^{\gamma - 1} - y_b^{\gamma - 1} \right)
\]

where \( y_b \) is the density at the outer edge. The condition for a vanishing asymptotic current is simply \( y_0 = y_b \). In order to relate the latter density to the external pressure, the transfield equation \( (22) \) can be reformulated in differential form and, making use of the definition of its integration constant \( C \) in Eq. \( (24) \), can be cast in the equivalent form

\[
\dot{y} = -\frac{2\omega^2 y^2 \dot{x}}{(\gamma - 2) \beta y^{\gamma - 1} + C}
\]

and the Bernoulli equation is simply

\[
\dot{x} = 2 / y \sqrt{\epsilon - C}
\]

Substituting \( \dot{x} \) from Eq. \( (30) \) in Eq. \( (22) \) we obtain

\[
\dot{y} ((\gamma - 2) \beta y^{\gamma - 2} + C / y) = -4\omega^2 / A \sqrt{\epsilon - C}
\]

that can be integrated between the axis and the outer edge of the outflow (\( y \) varies from \( y_0 \) to \( y_b \) and \( \bar{a} \) varies from 0 to 1)

\[
C \ln \left( \frac{y_b}{y_0} \right) + \frac{\beta (\gamma - 2)}{2} \left( y_{\gamma - 1} - y_{\gamma - 1} \right) = -4\omega^2
\]
significantly across the jet. This approximation is justified numerically. Pressure balance at the outer edge of the jet gives a relation between the external pressure and the axial density

\[ \tilde{P}_{\text{ext}} = \frac{\gamma - 1}{\gamma} \beta y_b^\gamma + \omega^2 x_b y_b^2 + y_0^2 (\epsilon - \beta y_b^\gamma - 1 - 2\omega^2 x_b y_b) \]  

(33)

where \( \tilde{P}_{\text{ext}} \) is defined by

\[ \tilde{P}_{\text{ext}} \equiv \frac{2\mu_0 r_A^3}{A^2} P_{\text{ext}}. \]  

(34)

Then the pressure balance equilibrium reduces to

\[ \tilde{P}_{\text{ext}} = \frac{\gamma - 1}{\gamma} \beta y_b^\gamma + \omega^2 x_b y_b^2 + y_0^2 (\epsilon - C) \]  

(35)

The system of Eqs. (32) and (33) establishes a relation between the external pressure \( \tilde{P}_{\text{ext}} \) and the axial density \( y_0 \). Further progress in making it explicit is possible in the case of slow and fast rotators, since simple solutions for \( \epsilon \) have been found in paper I.

4.1.1. Slow Rotators

Gas pressure is larger than magnetic pressure at the outer boundary for slow rotators. In this case \( \omega \ll 1 \), and therefore we have

\[ \tilde{P}_{\text{ext}} \equiv \frac{\gamma - 1}{\gamma} \beta y_b^\gamma \gg \epsilon - C \]  

(36)

The energy parameter \( \epsilon \) has been calculated for slow rotators in Paper I and is given by \( \epsilon = 1 + \beta + 3\omega^2 - g \). Considering \( g \) negligible with respect to \( \beta \) as a first approximation, Eq. (36) is given by

\[ y_b = \left( \frac{\gamma \tilde{P}_{\text{ext}}}{(\gamma - 1)\beta} \right)^{1/\gamma} \]  

(37)

Using the definition of \( \epsilon \), Eqs. (27) and (37), the Eq. (32) becomes

\[ \frac{1}{\gamma} \ln \left( \frac{\gamma \tilde{P}_{\text{ext}}}{(\gamma - 1)\beta y_0^\gamma} \right) + \left( \frac{\gamma - 2}{\gamma - 1} \right) \left( \frac{\gamma \tilde{P}_{\text{ext}}}{(\gamma - 1)\beta y_0^\gamma} \right)^{\gamma - 1} \]  

\[ = - \frac{4\omega^2}{\beta y_0^\gamma \sqrt{1 + \omega^2 - \beta(1 + y_0^\gamma - 1)}} + \frac{\gamma - 2}{\gamma - 1} \]  

(38)

The second terms of both the left and right hand sides are negligible with respect to the first terms and this equation can be simplified to

\[ \tilde{P}_{\text{ext}} = \frac{\gamma - 1}{\gamma} \beta y_0^\gamma \exp - \frac{4\omega^2 \gamma}{\beta y_0^\gamma \sqrt{1 + \omega^2 - \beta(1 + y_0^\gamma - 1)}} \]  

(39)

4.1.2. Fast Rotators

In this case, the gas pressure is negligible with respect to the magnetic pressure at the outer boundary. This means that

\[ \tilde{P}_{\text{ext}} = y_0^2 (\epsilon - C) \ll \epsilon - C \]  

(41)

Using Eq. (33) and condition (11), Eq. (32) becomes now

\[ \frac{C}{2} \ln \left( \frac{\tilde{P}_{\text{ext}}}{\epsilon - C} \right) - \frac{C}{\gamma - 1} \ln \left( \frac{C}{\beta} \right) \]  

\[ - \frac{\beta(\gamma - 2)}{(\gamma - 1)} \left( \frac{\tilde{P}_{\text{ext}}}{\epsilon - C} \right)^{\gamma - 1} - \frac{\gamma - 2}{\gamma - 1} C = - \frac{4\omega^2}{\sqrt{\epsilon - C}}, \]  

(42)

which has two simple solutions, when the external pressure becomes small, which are \( C \sim 0 \) and \( C \sim \epsilon \approx 3\omega \). In the latter case the poloidal current is given by

\[ I = \frac{A}{2r_A \mu_0 \omega} \left( 3\omega^{1/3} - \beta y_0^{-1} \right) \]  

(43)

If either \( \beta \) or the relative density at the boundary is small compared to unity, it reduces to

\[ I = \frac{3}{2} \frac{A}{r_A \mu_0} \omega^{1/3} \]  

(44)

It has been shown in paper I that the Alfvén radius grow with \( \omega \) faster than \( \omega^{1/3} \) for fast rotators. Then the current decreases as the rotator gets faster. Fast rotators do not carry the largest electric current. When \( \omega \) approaches its limit \( (\frac{3}{2})^2 \) corresponding to the very fast rotator the current approaches

\[ I = \left( \frac{3}{2} \right)^{3/2} \frac{A}{r_A \mu_0} \]  

(45)

Since \( r_A \) has been found in paper I to be proportional to \( \alpha^{-1/3} \), the total current increases with \( \alpha \).

4.2. Variation of the Current across the Flow

Differentiating the current as given by Eq. (21) with respect to the current along the axis.
Along the same lines as above, we can study the slow rotator case where the gas pressure dominates and the fast rotator case which has a strong magnetic pressure at the outer edge. In the former case, one finds that
\[ \frac{dI}{da} \sim \frac{2A\omega}{r_A^{1/2} \mu_0 \sqrt{1 + 3 \omega^2 - \beta - \beta \gamma^{-1}}} \] (47)

The slope of the variation of the poloidal current tends to vanish as \( \omega \) decreases. It is proportional to \( \frac{1}{r} \). For slow rotators the derivative is always positive and then the current is diffuse in the outflow. For fast rotators, \( C = \beta y_0^{-1} \ll \epsilon \) and one has
\[ \frac{dI}{da} \sim \frac{A \omega^{1/3} \gamma \ P_{\text{gas}}}{2 \sqrt{3} r_A \mu_0 \ P_B^*} \] (48)

The magnitude of the slope \( \frac{dI}{da} \) tends to vanish for very fast rotators since the gas to magnetic pressure ratio decreases with the rotation parameter. In the latter case the slope approaches small values more rapidly than in the slow rotator case. Another interesting point is that the gas to magnetic pressure ratio goes rapidly to zero across the jet as a function of radius. This means that all the current must be enclosed in a core around the axis for fast rotators, which should carry concentrated electric current. Thus it has been found analytically that slow rotators have a diffuse current while fast rotators carry concentrated electric current around the axis.

4.3. Evolution of the Current along the Flow

The variation of the current along one field line gives us fruitful informations on the structure of the outflow and on how the various quantities evolve from the source to infinity. In Fig. 11 the currents calculated at the Alfven surface, at the fast surface and asymptotically are plotted with respect to the relative radius, which is almost linearly related to \( \alpha = a/A \) with a slope equal to unity. For slow rotators, the poloidal electric current globally decreases from the Alfven surface to the asymptotic zone, which is constantly increasing from the polar axis to the edge of the jet. On the other hand the right panel shows that the current at the Alfven surface has a peak close to the polar axis for fast rotators. The current then decreases at larger distances from the axis which reveals the existence of a return electric current flowing around the central electric flow. This illustrates that the solutions obtained with this model carry return currents at other locations than at the polar axis, contrary to self-similar models.

![Fig. 11. Variations of the current along the flow for slow (left panel) and fast (right panel) rotators as functions of the relative radius. The electric current is calculated in the asymptotic region (solid lines), at the Alfven surface (dashed lines) and at the fast magnetosonic surface (long dashed lines).](image)

4.4. Influence of Source Properties

We plot in Fig. 12 the total asymptotic poloidal current in the jet as a function of the confining pressure for different types of rotators ranging from slow to very fast ones. All other parameters are kept constant. The external pressure can be reduced until the jet reaches unphysical size. The total current diminishes as the external pressure drops for all types of rotators but never approaches a constant non-vanishing limit for the smallest values of the pressure, the mass to magnetic flux ratio on the axis \( \alpha_0 \). The left panel of Fig. 13 represents the variations of the asymptotic poloidal current with the relative radius for various values of \( \Omega \). As the rotation increases, the current first increases but soon starts to decrease. Moreover the maximum current does not correspond to the largest rotation rate. On the right panel of Fig. 13, the current is plotted for different values of \( \alpha_0 \) for a given \( \Omega \). The larger the mass to magnetic flux ratio, the more the properties of the outflow resemble those of a slow rotator. The current profile changes from a concentrated one, signature of a fast rotator, to a more diffuse one for the largest \( \alpha_0 \). The total current increases at the meantime. So jets with large mass loss rate also possess a large current.

4.5. Influence of the External Pressure

We plot in Fig. 13 the total asymptotic poloidal current in the jet as a function of the confining pressure for different types of rotators ranging from slow to very fast ones. All other parameters are kept constant. The external pressure can be reduced until the jet reaches unphysical size. The total current diminishes as the external pressure drops for all types of rotators but never approaches a constant non-vanishing limit for the smallest values of the pressure.
Fig. 12. Plots of the asymptotic electric current profile for different values of constant angular velocity $\bar{\Omega}$ (left panel) and of the mass to magnetic flux ratio on the axis $\bar{\alpha}_0$ (right panel). Heavy solid lines correspond to slow rotators (left panel) and to small $\bar{\alpha}_0$ (right panel), while fast rotators (left panel) and large $\bar{\alpha}_0$ are plotted with heavy long dashed lines. Thin dashed lines correspond to intermediate values.

Fig. 13. Variations of the asymptotic electric current with the external confining pressure for various types of rigid rotators. The solid lines correspond to the fastest rotators while the dashed lines stand for slow rotators. $Q = 3.1$, $\bar{\alpha}_0 = 2.5$ and $\bar{\Omega}$ varies from 0.1 to 15 corresponding to $\omega$ varying from 0.1 to 1.8.

for smaller ones. For very fast rotators the current varies little with external pressure.

It would have been interesting to reach a conclusion on whether the asymptotic poloidal current vanishes or not in the limit of vanishing confining pressures. However, from a practical point of view, it appears that a significant residual current remains, even for exceedingly small, but non-vanishing, confining pressure.

4.6. Differential Rotators

We now investigate solutions with large gradients of the angular velocity, i.e. $\dot{\omega} \gg \dot{\alpha}$. Eq. (25) can be written as

$$ (\gamma - 1) \beta y^{\gamma - 1} \dot{y} + 2 \omega^2 xy^2 (\dot{y}/y + \dot{\omega}/\omega) = 0 $$

(49)

In this case the transfield equation can be integrated neglecting the relative derivative of the radius with respect to the relative derivatives of the density and of the rotation parameter. The integral is

$$ \frac{\gamma - 1}{\gamma} \beta y^{\gamma} + \omega^2 xy^2 = \beta y_0^{\gamma - 1} $$

(50)

Eq. (49) can be transformed using Eq. (21) into an equation for the current, that we will note $I_{\text{diff}}$, the solution of which is

$$ I_{\text{diff}} = \frac{A}{r_{\text{A}}} \frac{\gamma - 1}{\gamma} \beta y h \left( y_{\text{b}}^{\gamma - 1} - y_{\text{b}}^{\gamma - 1} \right) $$

(51)

This is different from the solution for the rigid rotator case, that can be noted $I_{\text{rig}}$. The relation between them is

$$ I_{\text{diff}} = \left( \frac{\gamma - 1}{\gamma} \right) \frac{2}{y_{\text{b}}} I_{\text{rig}} $$

(52)

This shows that the total current for differential rotators with large gradients of angular velocity will be larger since the density on the boundary is small compared to unity. This can clearly be seen in the left panel of Fig. 14 where the current is plotted with respect to the radius for different types of differential rotators. The largest values of the current correspond to profiles where the gradients of the angular velocity are positive and are the largest, namely for profiles of type $\Omega_2$, where the angular velocity takes half of its value at the middle of the outflow. Fig. 14 shows that the profile of the angular velocity is of prime importance, and that variations of the entropy with flux have a lesser influence on the current profile. Thus jets from differential rotators will carry a larger current and might be more collimated than rigidly rotating outflows.

5. Comparison between Numerical Results and a Simplified Model

In a review of the theory of magnetically accelerated outflows and jets from accretion disks, Spruit (1994) discusses...
the asymptotic wind structure. As in paper I, using his simplifications and method, we find that 

$$xy = 1 - \left( \frac{\alpha}{\alpha_*} \right)^{4/3} \left( \frac{r_A}{r_*} \right)^2.$$  

(53)

The net current from this simplified analytical model, that we will note $I_{\text{simp}}$, is defined by Eq. (21). It is given in the present case by

$$I_{\text{simp}} = \frac{9\omega A}{5\mu_0 r_*} \left( \frac{\alpha}{\alpha_*} \right)^{1/3} \left( 1 - \left( \frac{5\alpha}{9\alpha_* \omega^2} \right)^{2/3} \right).$$  

(54)

Thus the current is proportional to the angular velocity and the mass loss rate with the following dependencies

$$I_{\text{simp}} \propto \Omega \dot{M}^{1/3}$$  

(55)

The current can also be given as a function of the rotation parameter $\omega$ and of the Alfvén radius by

$$I_{\text{simp}} \approx \frac{3\omega A}{2\mu_0 r_A}.$$  

(56)

We have plotted this analytical solution with respect to $\omega$ in Fig. 13 together with the corresponding numerical solution. As $\omega$ increases and passes 0.5, the two solutions separate in the intermediate rotator region to converge again in the limit of very fast rotators. As shown previously the current increases with respect to $\omega$, for slow rotators and diminishes in the other limit. So the analytical results we have found for the current are in qualitative agreement with the real value.

The current can also be given as a function of the rotation and of the Alfvén radius by

$$\frac{I}{\rho A} = \frac{A^2}{r_*^2} \omega^2 xy = \frac{A}{r_*^2} \Omega \frac{\omega}{\alpha}.$$  

(57)

Using the previous Eq. (54), the Poynting flux for the above simplified analytical model is given by

$$S_{\text{simp}} = \frac{A}{\rho A r_A} \left( \frac{\alpha}{\alpha_*} \right)^{1/3} \left( 1 - \left( \frac{5\alpha}{9\alpha_* \omega^2} \right)^{2/3} \right).$$  

(58)

Thus the Poynting flux scales with the rotation and the mass loss rate as

$$S_{\text{simp}} \propto \Omega^2 \dot{M}^{-2/3}.$$  

(59)

This analytical solution is plotted with respect to the relative radius together with the numerical results with the same input parameters. The agreement is good all across the outflow, and Eq. (58) well reproduces the behavior of the asymptotic Poynting flux. Eq. (58) can be combined with the constraint on the boundary mass density $\rho_b$ given in paper I by

$$[S^2 H]_{\text{slow}} \leq [S^2 H]_{\text{fast}},$$

where the specific enthalpy $H$ is given at the slow and fast surfaces. Thus the asymptotic density at the outer edge of the outflow has an upper bound in terms of quantities defined in the inner part of the outflow close to its source. The wind carries both kinetic and magnetic energy, the asymptotic ratio of these, at large distance, is a measure of the importance of the magnetic field.

---

**Fig. 14.** Plots of the electric current profiles across the flow with respect to the relative radius $r_{rel} = r/r_*$. Left panel shows differential angular velocities and right panel shows differential specific entropies. Note the difference of ranges between different panels.

**Fig. 15.** Comparison of numerical results (solid line) and analytical solutions (dashed line) of the asymptotic electric current $I$ with respect to the rotation parameter $\omega$.

**The Poynting Flux** It is also interesting to calculate the Poynting flux per unit escaping mass which can be written as $S = \Omega r B_\phi / \mu_0 \alpha = I \Omega / \alpha$. Using our dimensionless variables it can be expressed as

$$S = \frac{A^2}{\mu_0 \rho A r_A} \omega^2 xy = \frac{A}{\rho A r_A} I \omega.$$

Moreover, in the asymptotic regime, most of the magnetic field is dominated at the outer edge of the flow. Effects have the most important influences on solutions. The specific entropy however has little influence on their asymptotic magnetic field. In the case of fast rotators, rotational and mass loss rate parameters have been obtained. This relation combined with the asymptotic solution gives the asymptotic current as a function of the confining pressure. An analytical solution for the poloidal current has also been obtained in the case of the fast rotator in terms of the rotation parameter and the Alfvén radius. The current in slow rotators is diffuse in the outflow while fast rotators carry a concentrated electric current around the axis. The solutions obtained with our model can carry return currents out of the polar axis, contrary to self-similar models. The comparison between numerical results and approximate analytic solutions shows the latter to be good qualitative estimators of the real value.

Non constant profiles of rotation and, to a lesser extent of entropy, cause the solutions to change drastically. For example, the largest asymptotic poloidal velocity can be located either on the axis or at the outer edge according to the profile of $\Omega(a)$. It has been possible to find solutions resembling observed flows such as central jets with important momentum surrounded by a larger outflow. Large currents can be generated by differential rotators if the gradient of the angular velocity is large and the angular velocity does not vanish on the outer edge of the flow.

Thus our model makes it possible to relate the properties of the asymptotic part of an outflow to those of the source. These asymptotic equilibria can be used as input estimators of the real value.

Acknowledgements. We would like to thank Kanaris Tsinganos for his remarks as referee that helped to clarify some of the derivations and discussions of equations.

Fig. 16. Comparison of numerical results (solid line) and analytical solutions (dashed line) for the Poynting flux $S$ across the outflow as functions of the relative radius $r_{rel} = \frac{r}{r_{jet}}$. An analytic solution for the poloidal current has also been obtained in the case of the fast rotator in terms of the rotation parameter and the Alfvén radius. The current in slow rotators is diffuse in the outflow while fast rotators carry a concentrated electric current around the axis. The solutions obtained with our model can carry return currents out of the polar axis, contrary to self-similar models. The comparison between numerical results and approximate analytic solutions show the latter to be good qualitative estimators of the real value.
