VLT and NTT Observations of Two EIS Cluster Candidates.

Detection of the Early-Type Galaxies Sequence at $z \sim 1^*$

Abstract. Optical data from the ESO VLT-UT1 Science Verification observations are combined with near-infrared data from SOFI at the NTT to obtain optical-infrared color-magnitude diagrams for the objects in the fields of two EIS cluster candidates. In both cases, evidence is found for a well-defined sequence of red galaxies that appear to be significantly more clustered than the background population. These results suggest that the two systems are real physical associations. The $(R-K_0)$, $(I-K_0)$ and $(J-K_0)$ colors of the red sequences are used, in conjunction with similar data for spectroscopically confirmed clusters, to obtain redshift estimates of $z \sim 0.9$ and $z \sim 1.0$ for these two systems. These results make these EIS cluster candidates prime targets for follow-up spectroscopic observations to confirm their reality and to measure more accurately their redshift.

Key words: Galaxies: clusters: general – large-scale structure of the Universe – Cosmology: observations

1. Introduction

Growing evidence for the existence of clusters at $z \sim 1$ and beyond makes the identification and study of these systems of great interest for probing galaxy evolution and cosmological models. However, the number of confirmed systems at these high redshifts is currently very small, precluding any robust statistical analysis. The largest sample of spectroscopically confirmed clusters has been selected from ROSAT deep X-ray observations (Rosati et al. 1998, Rosati 1998), while a few other $z \sim 1$ clusters have been discovered in the surroundings of strong radio sources (e.g., Dickinson 1996; Deltorn et al. 1997), or using infrared observations (e.g., Stanford et al. 1997). Although X-ray and infrared searches are very effective in identifying real clusters, their ability to cover large areas of the sky is presently limited, and these methods are not likely to produce large samples of very distant clusters in the short-term. On the other hand, with the advent of panoramic CCD imagers, optical wide-angle surveys have become competitive in identifying cluster candidates up to $z \sim 1$. Examples of such surveys, suitable for cluster searches, include those of Postman et al. (1996), Postman et al. (1998) and the ESO Imaging Survey (EIS, Renzini & da Costa 1997), which cover 5, 16 and 17 square degrees, respectively, reaching $I_{AB} \lesssim 24$. These surveys are currently being used for systematic searches of galaxy cluster candidates employing objective matched-filter algorithms (e.g., Postman et al. 1996). In the case of the EIS project, about 300 candidates have been identified, over the redshift interval $0.2 \lesssim z \lesssim 1.3$, out of which 79 are estimated to have $z \gtrsim 0.8$ (Olsen et al. 1998a, b; Scodeggio et al. 1998). However, only with additional observations can these optically-selected high-redshift candidates be confirmed. Establishing the global success rate of this technique (and its possible redshift dependence) is extremely important for the design of future wide-field optical imaging surveys. Indeed, these surveys may play a major role in significantly increasing the number of known distant clusters, thus making them useful tools for probing the high-$z$ universe.

As a test case, two EIS cluster candidates identified in EIS patch B (EIS 0046-2930 and EIS 0046-2951; Olsen et al. 1998b), were observed with the VLT Test Camera (VLT-TC) as part of the ESO VLT-UT1 Science Verification (SV; see Leibundgut, De Marchi & Renzini 1999).
Table 1. Summary of VLT-TC and SOFI Observations

| Cluster     | Filter | $t_{int}$ (seconds) | seeing (arcsec) |
|-------------|--------|---------------------|-----------------|
| EIS 0046-2930 | V      | 2700                | 0.9             |
|             | R      | 2700                | 0.8             |
|             | I      | 1500                | 0.9             |
|             | J      | 3000                | 0.8             |
|             | Ks     | 2400                | 1.1             |
| EIS 0046-2951 | V      | 2700                | 1.1             |
|             | I      | 1600                | 0.8             |
|             | J      | 3000                | 1.3             |
|             | Ks     | 3000                | 0.9             |

The IR J and Ks band images were obtained on October 8 and 9, 1998 using the SOFI infrared spectrograph and imaging camera (Moorwood, Cuby & Lidman 1998) at the NTT. SOFI is equipped with a Rockwell 1024 CCD detector that, when used together with the large field objective, provides images with a pixel scale of 0.29 arcsec, and a field of view of about $4.9 \times 4.9$ arcmin. The full set of SOFI observations will be described elsewhere (Jørgensen et al. 1999); here we describe only those for the fields including the two cluster candidates. Total integration times and the seeing measured on the combined images are given in Table 1. The data were reduced using the Eclipse data analysis software package (Devillard 1998), developed to combine jittered images. The resulting combined images were then input to the EIS pipeline for astrometric and photometric calibrations using observations of standard stars given by Persson (1997). From the scatter of the photometric solution we estimate the zero-point uncertainty in the J and Ks bands to be $<0.1$ mag.

In order to facilitate the analysis of the whole dataset, the images from the EIS-wide survey were resampled to a common reference frame, centered on the initial estimate of the two candidate cluster positions, using the Drizzle routine of the EIS pipeline. The resampled images have the same pixel size as the SOFI images. To improve the sensitivity to faint objects the resampled EIS-wide and SOFI images were combined to produce one very deep $B + V + I + J + Ks$ image for each field. This image has a sufficiently large field of view ($4.9 \times 4.9$ arcmin) to allow a reliable estimate of the background source density to be obtained (see Section 3). The source extraction software SExtractor (Bertin & Arnouts 1996) was subsequently used to detect sources in these deep images, while measuring the flux parameters for each individual passband in the separate images. Magnitudes and colors were measured using a 4 arcsec diameter aperture.

Also all available VLT images were coadded to produce the $V + R + I$ and $V + I$ images shown in Figure 1. The resulting images are considerably deeper than those from EIS, and also have much better resolution. This procedure has allowed us to reach approximately the same limiting magnitude in both fields ($I \sim 25.0$ at about $2\sigma$). Even though the transparency during the observations of the EIS 0046-2930 field was poor, this was compensated by the

Using the available multicolor data from EIS-wide plus SOFI, we derived $(I - Ks) - Ks$ CM-diagrams for all galaxies within 1 arcmin of the nominal candidate cluster centers. From these diagrams, a tentative color-based selection was made, dividing galaxies into cluster candidate members and foreground/background objects. Based on this selection, we computed for each cluster candidate a new position, obtained as the flux-weighted center of mass of the candidate members. An identical procedure was carried out using the SOFI data only, leading to very similar results. In both cases the new positions were found to be within 0.4 arcmin of the position given in the EIS catalog (Olsen et al. 1998b). Note that this corresponds to the pixel size (0.45 arcmin) of the maximum-likelihood map used in the EIS cluster finding procedure.

3. Results

Table 2 gives the original cluster candidates coordinates, the new flux-weighted positions as described above, the significance of the detection, the Abell richness and the estimated redshift from the EIS catalog, as listed in Olsen et al. (1998b) and the new redshifts derived below using the CM-diagrams from the combined VLT-TC and SOFI data. All coordinates are in J2000. Note that the estimate of the Abell richness for distant clusters is quite uncertain, but it serves to indicate their relative richness.

3.1. EIS 0046-2930

In the EIS candidate clusters catalog this object was identified only in $I$-band, and assigned a redshift of $z_{EIS} \sim 0.6$. However, visual inspection of the original survey images of this field showed the presence of foreground “blue” galaxies and of a fainter red population, not detected in the $V$–band. Using the deeper optical (reaching $V \sim 26.0 - 26.5$) and the IR catalogs produced from the VLT-TC and from the SOFI images, we can study in greater detail this cluster candidate. The resulting four optical and IR CM-diagrams are shown in Figure 1, for all galaxies within the VLT-TC field of view. The upper panel shows the optical $(V - I) - I$ CM-diagram, where there is a suggestion for a concentration of galaxies at $(V - I) \sim 2.7$, just beyond the reach of the EIS color data. However, the scatter is large compared with that seen in clusters at intermediate redshifts (Olsen et al. 1998b), and cannot Fig. 1. Optical and infrared CM-diagrams for all galaxies in the VLT-TC field of EIS 0046-2930. The filled circles indicate the ten brightest, most likely cluster members based on a color selection as described in the text. These
Fig. 2. Combined VLT-TC images (see text) for EIS 0046-2930 ($V + R + I$, left panel) and EIS 0046-2951 ($V + I$, right panel). The field of view of these images is $\sim 90$ arcsec. The computed flux-weighted centers are marked by $\times$. The numbers indicate the magnitude ranking of the ten brightest, most likely cluster members as described in the text.

Fig. 3. Projected radial distribution of galaxies brighter than $Ks = 20$ within the SOFI field of EIS 0046-2930. The figure shows separately the distribution of galaxies within $1.7 < (J - Ks) < 1.9$ (solid line) and outside this color range (dashed line), both normalized to their respective backgrounds.

$(I - Ks) - Ks$ diagram shows a clear early-type sequence in the interval $Ks = 16.0 - 20.0$ at $(I - Ks) \sim 3.9$. Using the above magnitude range, the CM-relation is well-fitted by a linear relation with an estimated scatter of $\sim 0.15$ ($Ks < 18.5$), comparable to the estimated error in the color and in agreement with the color dispersion of morphologically classified early-type galaxies in high-$z$ clusters (Stanford, Eisenhardt & Dickinson 1998). The infrared $(J - Ks) - Ks$ diagram shows an even tighter sequence at $(J - Ks) \sim 1.8$, with a scatter of $\sim 0.1$ mag, again comparable with the estimated error in the color. The ten brightest galaxies (in the Ks band) for which $1.7 \leq (J - Ks) \leq 1.9$ and $(V - I) \geq 2.3$ are represented by filled circles in the CM-diagrams and are also numbered in Figure 2 according to their magnitude ranking. These objects are the most likely early-type galaxy members of EIS 0046-2930. The flux-weighted position of the “cluster” is also shown.

The projected radial distribution of objects brighter than $Ks = 20$ and within the color range $1.7 \leq (J - Ks) \leq 1.9$, is shown in Figure 3, in annuli 0.3 arcmin wide. The contrast of this bright red-sequence population relative to the background is clearly seen, while there appears to be no appreciable clustering for galaxies outside this color range. Even though the statistic is poor, the scale and amplitude of the overdensity associated to this population, a factor of $\sim 7$ within the innermost 0.3 arcmin, are similar to those observed by Dickinson (1996) for the cluster surrounding 3C 324 at $z \simeq 1.26$. To test the robustness of this results flanking fields with the same size of the VLT-TC field of view were extracted from the same SOFI image.
Optical and infrared CM-diagrams for galaxies in the VLT-TC field of EIS 0046-2951. The filled circles represent the ten brightest, most likely cluster members (marked in Figure 2) as described in the text.

Fig. 5. Projected radial distribution of galaxies brighter than $K_s = 20$ within the SOFI field of EIS 0046-2951. The figure shows separately the distribution of galaxies within $1.6 < (J - K_s) < 1.8$ (solid line) and outside this color range (dashed line), both normalized to their respective backgrounds.

On the presumption that EIS 0046-2930 is a real cluster, the color of the red sequence can be used to estimate its redshift. This can be achieved either by using synthetic stellar population models, or purely empirically using the colors of the red sequence of clusters of known redshift. Even though the available data are sparse, we have adopted the latter approach because it is model independent. We have used the spectroscopic redshifts and the CM-diagrams given by Stanford, Eisenhardt & Dickinson (1998) for their clusters at $z > 0.5$ and the $z = 1.273$ cluster of Stanford et al. (1997) to estimate the location of the early-type galaxies sequence in different passbands for clusters at $z \sim 1$. Interpolating these relations to the colors of the red sequence of EIS 0046-2930 ($(R - K) = 5.4$, $(I - K) = 3.9$, and $(J - K) = 1.8$) we consistently estimate its redshift to be $z_{CM} = 1.0 \pm 0.1$ (statistical uncertainty only).

3.2. EIS 0046-2951

In the EIS catalog this object was estimated to have a redshift of $z_{EIS} \sim 0.9$, being detected only in the $I$-band (Table 3). However, visual inspection of the $V-$ and $I-$ band EIS images suggested that this system could be an overlap of two concentrations at different redshifts. Using the deeper $V-$band image obtained with the VLT-TC we are now able to investigate the optical CM-diagram shown in Figure 3. Indeed, we find two concentrations of galaxies: one seen at $(V - I) \sim 1.6$ and another at $(V - I) \sim 2.6$. These colors correspond to redshifts $z \sim 0.25$ and $z \sim 0.7$, respectively. However, in the $(I - K_s) - K_s$ and $(J - K_s) - K_s$ CM-diagram the objects are located at $(I - K_s) \sim 3.5$ and $(J - K_s) \sim 1.7$, leading to a redshift estimate of $z_{CM} = 1.0 \pm 0.1$ (statistical uncertainty only).
both cases, in good agreement with the original estimate based on the matched-filter algorithm. In contrast to the previous cluster, the scatter of the red sequence in both colors is significantly larger (0.21 in \((I - Ks)\) and 0.19 in \((J - Ks)\)) and cannot be fully accounted for by the photometric errors in our data (\(< 0.15\) mag). The larger scatter may be due to a larger fraction of spiral galaxies in the “cluster”, or to a stronger contamination by foreground galaxies. As in the previous case, the most likely early-type cluster galaxies have been selected adopting a color-selection criterion similar to that described above. These galaxies, chosen to have \(1.5 \leq (J - Ks) \leq 1.9\) and \((V - I) \geq 2.3\), are identified in Figure 5 and in the right panel of Figure 2.

Figure 6 shows the projected radial distribution of color-selected candidate cluster members. In this case we find that the overdensity of the red sequence galaxies is \(\sim 5\), over the same radial distance as for the previous cluster. The smaller overdensity of this candidate cluster (and perhaps the larger fraction of spirals) is consistent with the lower original estimate of its richness (Table 2). Note that a 3\(\sigma\) detection at approximately the same redshift was obtained applying the matched-filter algorithm to the \(Ks\) data. As for the previous object, the analysis of flanking fields from the SOFI image gives further support to the reality of the observed concentration in color and projected separation, suggesting the existence of a physical association.

4. Summary

We have used deep \(V\)- and \(I\)-band images of two EIS cluster candidates taken during the ESO VLT-UT1 Science Verification observations to investigate the reality of these clusters. The VLT data were complemented by infrared data taken with SOFI at the NTT. Optical, IR, and optical-IR CM-diagrams have been constructed to search for the presence of the red-sequence typical of bright early-type galaxies in clusters.

In the case of EIS 0046-2930 we find a well-defined sequence at \((I - Ks) \sim 3.9\) and \((J - Ks) \sim 1.8\). These galaxies are also concentrated relative to the background suggesting the existence of a cluster at \(z = 1.0 \pm 0.1\). The evidence for the other candidate, EIS 0046-2951, is less compelling even though we find a sequence at \((I - Ks) \sim 3.5\) and \((J - Ks) \sim 1.7\), leading to an estimated redshift of \(z = 0.9 \pm 0.15\), consistent with its original estimate. However, the scatter in the CM-diagrams is large and the density contrast of the “cluster” relative to the background smaller. In any case, a final conclusion on whether these systems are real physical associations at high-redshift must await spectroscopic observations.

These results demonstrate once again the importance of this strategy remains to be empirically determined, e.g. for the actual complement of ESO telescopes and instruments, and the present paper represents a first step in this direction.
