ABSTRACT
We report on a new Be/X-ray pulsar binary located in the Wing of the Small Magellanic Cloud (SMC). The strong pulsed X-ray source was discovered with the Chandra and XMM-Newton X-ray observatories. The X-ray pulse period of 1062 s is consistently determined from both Chandra and XMM-Newton observations, revealing one of the slowest rotating X-ray pulsars known in the SMC. The optical counterpart of the X-ray source is the emission-line star 2dFS 3831. Its B0-0.5(III)e-+ spectral type is determined from VLT-FLAMES and 2dF optical spectroscopy, establishing the system as a Be/X-ray binary (Be-XRB). The hard X-ray spectrum is well fitted by a power-law with additional thermal and blackbody components, the latter reminiscent of persistent Be-XRBs. This system is the first evidence of a recent supernova in the low density surroundings of NGC 602. We detect a shell nebula around 2dFS 3831 in Hα and [O III] images and conclude that it is most likely a supernova remnant. If it is linked to the supernova explosion that created this new X-ray pulsar, its kinematic age of (2 – 4) × 10^4 yr provides a constraint on the age of the pulsar.

Key words: X-rays: binaries – stars: emission-line, Be – Magellanic Clouds.

1 INTRODUCTION

The Small Magellanic Cloud (SMC) is host to a large population of ~50 high-mass X-ray binaries (HMXBs), comparable to the number known in the Galaxy (e.g. Haberl & Pietsch 2004, Coe et al 2005, Reig 2011). However, unlike the Galactic population, all of these systems but one are Be/X-ray binary (Be-XRB) systems, with the exception (SMC-X1) containing a supergiant companion instead (Webster et al. 1973).

The Wing of the SMC is the region linking the eastern side of the SMC to the Bridge. Despite its lower content of gas, dust, and stars, it had a major star forming event ~11 Myr ago and appears, as expected, deficient in Be-XRBs (Antoniou et al. 2010). Note however that the coverage of the SMC Wing by X-ray observations has been sparser than that of the Bar. Each new discovery of a Be-XRB in the SMC Wing is therefore particularly noteworthy (e.g. McGowan et al. 2007).

We have conducted Chandra and XMM-Newton observations of the far eastern region of the Wing, concentrating on the star forming region NGC 602. The full description of these observations will be presented in a forthcoming paper (Oskinova et al., in preparation). In this letter, we concentrate on one bright X-ray source located near NGC 602 in projection and coinciding with the emission-line star 2dFS 3831 (R.A. =1°27′46.03″, Dec. =−73°32′56.42″, J2000.0), which is revealed as a Be-XRB. Based on the results of section 2.2 throughout this paper we will refer to the X-ray source as SXP 1062 following the nomenclature of Coe et al. (2005) for SMC X-ray pulsars.

The stellar population of NGC 602 (which comprises three star clusters: NGC602 A, B, and C) has been studied in detail. In addition to very old stars of 6-8 Gyr, likely the SMC field population, the NGC 602 clusters contains young stars of ~4-5 Myr (Westerlund 1964, Hutchings et al. 1991, Cignoni et al. 2009). The significant number of young stellar objects detected in the NGC 602A cluster (Carlson et al. 2007, Gouliermis et al. 2007) suggests that star formation is still ongoing. As for what initially triggered the formation of these clusters, the low density environment in the Wing of the SMC hints at an additional mechanism.

* E-mail: vhb@roe.ac.uk
acting along with gravitational collapse. NGC 602 is located at the intersection of three H I shells, and suggested that its formation is the result of the interaction of two expanding shells ~7 Myr ago. Schmalzl et al. (2008) proposed instead that star formation was possibly induced by encounters with the Large Magellanic Cloud or the Milky Way. NGC 602 is associated with SGS-SMC1, the only Hα supergiant shell known in the SMC. The discovery of a Be-XRB in this area (only ~7' to the west of NGC 602A) provides important clues to the star formation history in the Wing and the evolution of large-scale structures in the interstellar medium.

This letter is organized as follows. We describe the X-ray observations and analysis in section 2. In section 3, we present the spectroscopy of the optical counterpart. We discuss the properties and environment of SXP 1062 in section 4, and present our conclusions in section 5.

2 X-RAY OBSERVATIONS

The X-ray data were obtained with the ACIS-I camera on the Chandra X-ray Observatory and with the EPIC cameras onboard XMM-Newton. The Chandra observations consisted of 11 separate exposures acquired between 2010-03-31 and 2010-04-29 (effective exposure time of 290.7 ks), while 4 separate exposures were obtained with XMM-Newton between 2010-03-25 and 2010-04-12 (EPIC-pn effective exposure time of 162.5 ks). The data were reduced using the most up-to-date versions of the corresponding data reduction software. The X-ray source CXO J102745.97-733256.5 (=SXP 1062) coinciding with the optical emission-line star 2dSFR 3831 is detected in each of these 15 exposures. In the Chandra observations, the positional uncertainty (1σ) of the X-ray source is 0.9′. The source was also detected during an XMM-Newton slew on 2009-11-16. Interestingly, the source was not detected in the ROSAT All Sky Survey, although at its present luminosity it would have been bright enough at an expected ROSAT PSPC count rate of 0.01 counts s⁻¹.

2.1 Spectral analysis

Figure 1 shows the combined background-subtracted Chandra and XMM-Newton spectra of SXP 1062. The Chandra spectra were extracted from a 12′×8′ circular region and the background was extracted from a concentric annular region of radii 12′×8′ and 19′×2′ which was free of sources. Likewise, the XMM-Newton spectra were extracted from a 32′×28′ circular region and the background from 4 adjacent circular regions free of sources with radius 45′.

As a first step the background-subtracted Chandra and XMM-Newton spectra of SXP 1062 were simultaneously fitted using a simple absorbed power-law model. The best-fit parameters, listed in Table 1 and Figure 1, imply an absorbed flux in the energy range 0.2-12.0 keV of $1.8\times 10^{-12}$ erg cm⁻² s⁻¹. This corresponds to an intrinsic X-ray luminosity in this same energy range of $L_X=6.9\times 10^{35}$ erg s⁻¹ assuming a distance modulus of 18.7 appropriate for the Wing (e.g. Cignoni et al. 2009), or $L_X=8.2\times 10^{35}$ erg s⁻¹ for the standard SMC distance modulus of 18.9 (e.g. Harries et al. 2003). The photon index $\Gamma$ of ~0.75 is typical of X-ray pulsar binaries (e.g. Yokogawa et al. 2003) and a signature of accretion onto a strongly magnetized neutron star.

The simple power-law model suggests some emission excess below 1 keV and at high energies. As a next step, we added a blackbody component, which statistically improved the fit (see Table 1).

The observed X-ray flux is similar to that of the previous model, but the X-ray luminosity decreases by ~10%. We also tried a model for which a thermal plasma component with SMC abundances is included instead of a blackbody. Similarly to the blackbody, the addition of a thermal component to the power-law model improves the fit. In this case, the intrinsic X-ray luminosity is only marginally greater by ~1% compared to the simple power-law model.

Finally, the best fit is achieved by adding simultaneously a thermal and a blackbody component to the power-law (see Table 1 and Figure 1). The flux for this model (PBT in Table 1) is $f_{X}=1.66_{-0.25}^{+0.19}\times 10^{-12}$ erg cm⁻² s⁻¹, corresponding to an intrinsic luminosity $L_X=6.3_{-0.6}^{+0.7}\times 10^{35}$ erg s⁻¹ for a distance modulus of 18.7.

The column densities are well constrained by spectral fitting, albeit the values slightly differ depending on the model. Using the best-fit values, we note that the H column densities in Table 1 imply $A_V=0.63\pm 0.08$ mag for the $N_{H}/A_V$ ratio of $1.87\times 10^{-22}$ cm⁻², i.e. $E_{B-V}=0.20\pm 0.28$ assuming $R_V=3.1$. This range is in good agreement with the $E_{B-V}=0.19$ value computed by comparing the value $(B-V)=0.04$ of 2dFS 3831 (Massey 2002) with the intrinsic value $(B-V)_0=-0.23$ of a B0.5-III star (Wegner 1994) given the uncertainties on the photometry and spectral type (see section 5 for the optical spectroscopy of 2dFS 3831).

2.2 Timing Analysis

The photon arrival times were corrected for the solar system barycenter. We searched for pulsations in the X-ray light curves in the soft and hard energy bands (0.4 keV—1.5 keV, 2.0 keV—7.2 keV) and a total energy band (0.4 keV—7.2 keV), using fast Fourier transform and light-curve folding techniques as implemented in the timing analysis software xronos.

Figure 2 shows the inferred Chandra and XMM-Newton power density spectra in the soft and hard energy bands with a clear peak at a frequency of $9.4\times 10^{-4}$ Hz $(P=1062\text{ s})$. This coherent X-ray pulse period establishes the source as a binary X-ray pulsar. The pulse profiles folded with this period are shown in Figure 3.

The light-curves used to compute the XMM-Newton power
Table 1. Best-fit parameters of the spectral models. The code for the different components of each model is: “P” for power-law, “B” for blackbody, and “T” for optically thin thermal emission with SMC abundances.

3 OPTICAL SPECTROSCOPY

From its X-ray position with subarcsecond precision from Chandra images, the optical counterpart to SXP 1062 is identified as 2dFS 3831 (Evans et al. 2004). We observed this star with the VLT FLAMES instrument (Pasquini et al. 2002) on 2010 October 25 as part of a spectroscopic survey of massive stars in NGC 602 complementing our X-ray observations. Spectra were obtained in the Medusa-fibre mode of FLAMES using the LR02 setting of the Giraffe spectrograph (3960–4564 Å, R = 7000, e.g. Evans et al. 2011). Five pairs of 1800 s exposures were obtained. The standard data processing (bias subtraction, fibre location, summed extractions, division by flat-field, wavelength calibration) was done using the ESO Common Pipeline Library FLAMES reduction routines (v.2.8.7). Additionally, heliocentric correction and subtraction of a median sky spectrum were performed (for details see e.g. Evans et al. 2011). The spectra from all the exposures were then normalized and merged. The 2dF spectra of this star were also retrieved. These two spectra cover the regions from 3800 to 7000 Å, with resolving powers of 1500 and 2500 respectively (Evans et al. 2004). Figure 4 shows the VLT FLAMES and 2dF spectra of 2dFS 3831. The VLT FLAMES spectrum has been smoothed and rebinned to an equivalent resolving power of R = 4000.

A weak He \( \lambda \) 44542 absorption line is visible in the VLT FLAMES spectrum and there is a hint of a weak He \( \lambda \) 44686 line in the 2dF spectrum, but He \( \lambda \) 44200 is absent, suggesting a spectral type around B0-0.5 following the classification adopted by Evans et al. (2004).

Several characteristics attributable to a circumstellar disc indicate that 2dFS 3831 is a classical Be star. Fe \( \lambda \) 44179 and Fe \( \lambda \) 44233 emission lines typical of some early Be stars (e.g. Slettebak 1982) are visible in the VLT FLAMES spectrum. The H\( \alpha \) emission seen in the 2dF spectrum (see the right panel in Fig 5) is relatively strong with an equivalent width (EW) of -23 Å. There is significant H\( \beta \) emission, plus emission in the core of the other Balmer lines (double-peaked in the VLT FLAMES spectrum) and apparent infilling of the H\( \gamma \) absorption lines. Two Micron All Sky Survey (2MASS; Skrutskie et al. 2006) JHK photometry also indicates a clear infrared excess when compared with expected colors for a
B0-0.5 spectral type (Wegner 1994). The double-peaked emission in the Balmer lines is not due to oversubtraction of nebular features present in the median sky spectrum. Also, given the relative weakness of the nebular emission lines in the mean sky spectrum, the emission in the core of the Balmer lines is most likely dominated by circumstellar material and not by nebular contamination.

The observed magnitude \((V=14.36, B=14.32;\) Massey 2002) and a range of reasonable extinction estimates (including both the interstellar and circumstellar components) lead to an absolute magnitude consistent with a B0-0.5 giant \((\) Walborn 1972; Vacca et al. 1996). We thus determine the spectral type of 2dFS 3831 as B0-0.5(III)\(\ell\)+, where ‘\(\ell\)’ signifies the presence of Fe ii. This corresponds to a typical effective temperature \(T_{\text{eff}} \approx 26,000 \) K and an evolutionary mass \(M \approx 15 M_\odot\) at SMC metallicity (cf. Trundle et al. 2007).

We estimated the radial velocity of 2dFS 3831 from the VLT FLAMES spectrum by fitting Gaussian profiles to the wings of H\(\gamma\), H\(\delta\), H\(\epsilon\), H\(\iota\) 14143, and He i 14388. The average of all measurements is 167 km s\(^{-1}\) with a standard deviation of 13 km s\(^{-1}\). This is consistent with the mean velocity of massive stars in the SMC (Evans & Howarth 2008), and also with the gas velocities measured by Nigra et al. (2008) across the N 90 H \(\alpha\) region ionized by NGC 602A. Thus, we do not see any evidence that the HMXB acquired a high space velocity following the supernova explosion.

4 DISCUSSION

4.1 The properties of SXP 1062

SXP 1062 is only the third SMC X-ray pulsar with a spin period larger than 1000 s (Laycock et al. 2010). These slowly rotating pulsars are particularly interesting because they represent a challenge for the theory of spin evolution of a neutron star in a close binary system (e.g. Ikhansov 2007).

According to the Corbet diagram for SMC Be-XRBs relating spin and orbital period (Corbet et al. 2009), we expect SXP 1062 to have a binary period of \(\sim 300\) days. Such a long orbital period is also expected from the \(P_{\text{orb}}-\)EW(H\(\beta\)) diagram (Reig et al. 1997), from which our measured EW(H\(\beta\)) suggests an orbital period of \(\sim 100\) days. Note however that the maximum EW(H\(\beta\)) of the system, which probes the maximum size of the disc (and indirectly the orbital period), could be higher than our instantaneous measurement, so this period estimate should be taken as a lower limit.

SXP 1062 shares many characteristics with the class of persistent Be-XRBs (e.g. Reig 2011): a relatively low X-ray luminosity \(\sim 10^{34} - 10^{35}\) erg s\(^{-1}\), a slowly rotating pulsar with \(P > 200\) s, a relatively flat light curve with sporadic and unpredicted increases in intensity by less than an order of magnitude, and a lack of iron lines at \(\sim 6.4\) keV indicative of small amounts of material in the vicinity of the neutron star. A thermal excess of blackbody type, with a high temperature \((kT > 1\) keV) and a small emission area \((R < 0.5\) km, consistent with a hot spot at the polar cap of the neutron star) has recently been suggested as a common feature of persistent Be-XRBs (La Palombara et al. 2009). Such a component is also identified in the X-ray spectrum of SXP 1062, for which we infer a size of \(\sim 0.4\) km for the blackbody source from our best-fit models (section 2.1).

4.2 The environment of SXP 1062

A shell nebula is detected around SXP 1062 in the Magellanic Cloud Emission-line Survey (MCELS; Smith et al. 1999). H\(\alpha\) image and in the higher resolution CTIO 4m MOSAIC (Mueller et al. 1998) H\(\alpha\) image (see Figure 3). This shell is also detected in the MCELS [O iii] image, but hardly in [S ii]. We adopt below a distance modulus of 18.7. The shell is not uniform, with radii varying from 75" at the sharp rim on the northeast to 94" at the diffuse edge on the southwest. The peak surface brightness of the northeast rim is \(\sim 6 \times 10^{-17}\) ergs cm\(^{-2}\) s\(^{-1}\) arcsec\(^{-2}\), corresponding to an emission measure of 30 cm\(^{-6}\) pc. The width of the rim suggests that the shell thickness (\(\Delta R\)) is 5–10% of the shell radius (\(R\)). The longest emitting length at the shell rim is \(2R[1-(\Delta R/R)^2]^{1/2}\); thus, the rms density in the shell is \(1.3 \pm 0.3\) H-atom cm\(^{-3}\). The gas mass in the shell is 250 \(\pm\) 100 \(M_\odot\). This large mass indicates that the shell gas must be dominated by interstellar material.

The shell morphology resembles supernova remnants (SNRs) in the Magellanic Clouds. The X-ray images also suggest that diffuse X-ray emission possibly associated with a SNR may be present in the vicinity of SXP 1062 (Oskinova et al., in preparation). As the shell mass is much larger than the typical supernova ejecta mass, we assume that the shell is a SNR in the Sedov phase. The kinetic energy in the shell would be \(\sim 30\%\) of the supernova explosion energy. Adopting a canonical explosion energy of \(10^{51}\) ergs, the current shell kinetic energy is \(3 \times 10^{50}\) ergs, and implies a shell expansion velocity of 350\(\pm\)10 km s\(^{-1}\) and an age of 0.4\(R/V\)(=\(2\)–\(4\))\(\times\)10\(^4\) yr. This age is much larger than the cooling timescale of this low density gas, justifying an adiabatic shock for the Sedov phase. The
Discovery of a Be/X-ray pulsar binary and associated supernova remnant in the Wing of the SMC

5

5 CONCLUSION

We reported the discovery of a Be-XRB, SXP 1062, containing one of the slowest rotating X-ray pulsars in the SMC. We suggest that the shell nebula detected around this object is a SNR. Its estimated kinematic age of (2–4) × 10^4 yr is probably the age of the pulsar. This is, to our knowledge, the first discovery of a pulsar associated with a supernova remnant in the SMC.

ACKNOWLEDGMENTS

This study is based on observations obtained with XMM-Newton, an ESA science mission with instruments and contributions directly funded by ESA Member States and NASA, and the Chandra science mission. The software provided by the Chandra X-ray Center (CXC) in the application package CIAO and by the XMM-Newton in the package SAS was used. This research has made use of NASA’s Astrophysics Data System Service and the SIMBAD database, operated at CDS, Strasbourg, France. We thank Frank Winkler for providing the SMC MCELS images.
