Parameter Varying Mode Decoupling for LPV systems

Tamás Baár, Péter Bauer and Tamás Luspay

Institute for Computer Science and Control (SZTAKI), Budapest, Kende u. 13-17., 1111 Hungary (e-mail: baar.tamas@sztaki.hu)

Abstract: The paper presents the design of parameter varying input and output transformations for Linear Parameter Varying systems, which make possible the control of a selected subsystem. In order to achieve the desired decoupling the inputs and outputs of the plant are blended together, and so the MIMO control problem is reduced to a SISO one. The new input of the blended system will only interact with the selected subsystem, while the response of the undesired dynamical part is suppressed in the single output. Decoupling is achieved over the whole parameter range, and no further dynamics are introduced. Linear Matrix Inequality methods form the basis of the proposed approach, where the minimum sensitivity (denoted by the $H_\infty$ index) is maximized for the subsystem to be controlled, while the $H_\infty$ norm of the subsystem to be decoupled is minimized. The method is evaluated on a flexible wing aircraft model.

Keywords: Decoupled subsystems, Linear Parameter Varying systems, Generalized Kalman–Yakubovich–Popov lemma, Linear Matrix Inequality, Minimum Sensitivity, Mode Control

1. INTRODUCTION

Since its appearance, Linear Parameter Varying (LPV) systems theory became a well established field in control systems design with numerous application possibilities. Recent trends in systems engineering are pointing in the direction of reducing the complexity of the control problem. This can be achieved by reducing the order of the controller (Nwesaty et al., 2015), by designing fixed structure controllers (Adegas and Stoustrup, 2012), or by decoupling. The paper focuses on the latter one, where our general aim is to control a certain fraction of the system, without affecting other parts.

Various decoupling approaches can be found in the literature for LPV systems to achieve input-output decoupling. Mohammadpour et al. (2011) designs a static input-output decoupling by pre- and post- compensators based on the singular value decomposition of the steady state transfer function matrix. The method has the advantage that it does not introduce further dynamics to the open loop, however it does not guarantee decoupling over the whole frequency range. Lan et al. (2015) applies a dynamic decoupling for the LPV model for a hypersonic flight vehicle based on convex optimization with Linear Matrix Inequality (LMI) constraints. The $H_\infty$ norm of a virtual system which is composed by the controlled system and the no coupling reference model is minimized. (van de Wiel et al., 2018) presents a decoupling approach for quadrotor systems. The authors design an inverse based decoupling pre-filter which decouples the system into double integrators.

In the present paper we focus on subsystem decoupling for LPV systems. In recent years various approaches were introduced in order to assure decoupled control of selected dynamical modes of a system. However to the best of the knowledge of the authors, these methods are not extended to Linear Parameter Varying (LPV) systems. The common point for many of these methods is that they introduce input and output blending vectors to decouple modes and accordingly reduce the control design into a Single Input Single Output (SISO) problem. Danowsky et al. (2013) determines an optimal blend for the measurements which assures the isolation of the selected mode, and simultaneously computes an optimal blend for multiple control inputs to suppress the selected mode via a negative optimal feedback, while minimizing the control’s effect on other modes. (Pusch, 2018) introduces a joint $H_2$ norm based input and output blend calculation method which assures the controllability, observability and the independent control of selected modes.

In recent papers (Baár and Luspay, 2019) and (Baár et al., 2019) the authors presented a novel sensor and actuator blending approach for LTI systems, in order to assure decoupled control of individual modes with simple SISO controllers. The present paper extends these results to LPV systems. Our approach is based on the $H_\infty$ index and the $H_\infty$ norm for LPV systems, by seeking parameter-dependent input and output blend vectors which are maximizing the minimum sensitivity for a given mode, while minimizing the maximal one for the other subsystem. This way decoupling can be achieved between the dynamical modes.

The outline of the paper is as follows. Section 2 provides the necessary mathematical formulations, followed by Section 3 with the formal problem statement. The mode decoupling algorithm is presented entirely in Section 4. Numerical examples are reported in Section 5, followed by the concluding remarks.

2. MATHEMATICAL BACKGROUND

Basic mathematical notions and the required definitions are given in the section, which are used throughout the construction of the decoupling algorithm.
2.1 Linear Parameter Varying Systems

Our starting point is the state space formulation of continuous time LPV systems, given as:

\[
\begin{align*}
\mathcal{G}(\rho(t)) : \begin{cases}
\dot{x}(t) = A_1(\rho(t)) x(t) + B_1(\rho(t)) u(t), \\
y(t) = C_1(\rho(t)) x(t) + D_1(\rho(t)) u(t),
\end{cases}
\end{align*}
\]  

(1)

with the standard notation of \( x(t) \in \mathbb{R}^{n_x}, u(t) \in \mathbb{R}^{n_u} \) and \( y(t) \in \mathbb{R}^{n_y} \) being the state, input and output vector, respectively, depending on the continuous time variable \( t \). The trajectories of the time-varying scheduling vector \( \rho(t) \in \mathbb{R}^{n_\rho} \) are unknown apriori, but measurable on-line, and they are assumed to be constrained in the parameter variation set

\[
\mathcal{F}_P^\rho = \{ \rho(t) \in \mathcal{C}^1(\mathbb{R}_+, \mathbb{R}^{n_\rho}) : \rho(t) \in \mathcal{P}, \dot{\rho}(t) \in \mathcal{V}, \forall t \geq 0 \},
\]

(2)

where \( \mathcal{C}^1 \) is the class of piece-wise continuously differentiable functions, \( \mathcal{P} := \{ \rho \in \mathbb{R}^{n_\rho} : \rho_i \in [\bar{\rho}_i, \bar{\rho}_i] \} \), and \( \mathcal{V} := \{ \nu \in \mathbb{R}^{n_\rho} : \nu_i \in [\bar{\nu}_i, \bar{\nu}_i] \} \).

In the mode decoupling problem we assume that the system matrix functions are given in the following subsystem form:

\[
\begin{align*}
A(\rho) &= \begin{bmatrix}
A_1(\rho) & 0 \\
0 & A_2(\rho)
\end{bmatrix}, & B(\rho) &= \begin{bmatrix}
B_1(\rho) \\
B_2(\rho)
\end{bmatrix}, \\
C(\rho) &= \begin{bmatrix}
C_1(\rho) & C_2(\rho)
\end{bmatrix}, & D(\rho) &= \begin{bmatrix}
D_1(\rho) \\
D_2(\rho)
\end{bmatrix}.
\end{align*}
\]

(3)

For Linear Time Invariant (LTI) systems this form is called the modal form, which can be achieved by a suitable state transformation (Kailath, 1980). A similar structure for LPV systems has been developed, along with the construction of the corresponding parameter-dependent state transformation in (Luspay et al., 2018a), resulting in a block-diagonal and continuous \( A(\rho) \) function, where each block represents a dynamical mode of the parameter-varying dynamics.

For the ease of presentation we will assume that the system consists of only two subsystems, one which we would like to control (subscript \( c \)) and the one which should be decoupled (subscript \( d \)), where the latter may contain multiple modes. In (3) coupling between the subsystems appears only through the input-output, which we are intend to resolve in the paper.

2.2 Minimum sensitivity

A key notion in the decoupling approach is the minimum sensitivity (\( \mathcal{H}_\infty \) index) of a system, which is defined for LTI systems over a finite frequency domain as:

\[
|| \mathcal{G}_c(s) ||_{\mathcal{H}_\infty} := \inf_{\omega \in [\bar{\omega}, \bar{\omega}]} \sigma [ \mathcal{G}_c(j\omega) ],
\]

with \( \sigma \) denoting the minimum singular value and \( \omega, \bar{\omega} \) being the minimal and maximal frequency of interest. The computation of (4) can be done based on the Generalized Kalman-Yakubovich-Popov (GKY) lemma by using convex optimization, involving Linear Matrix Inequality (LMI) constraints (Wang and Yang, 2008).

The extension of the finite frequency \( \mathcal{H}_\infty \) index for LPV systems is defined as (Sun et al., 2013):

\[
|| \mathcal{G}_c(\rho) ||_{\mathcal{H}_\infty} := \inf_{\omega \in [\bar{\omega}, \bar{\omega}]} \sigma [ \mathcal{G}_c(j\omega, \rho) ], \forall \rho \in \mathcal{F}_P^\rho.
\]

(5)

which corresponds to the following time-domain definition:

\[
\inf_{\rho \in \mathcal{F}_P^\rho} \inf_{||u||_2 \neq 0} \frac{||y||_2}{||u||_2} > \beta
\]

(6)

over inputs \( u \in \mathcal{L}_2^{\rho} \), such that the following holds:

\[
\int_0^{\infty} \left( \Psi_{11} \dot{x}^T \dot{x} + \Psi_{12} \dot{x}^T x + \Psi_{21} x^T \dot{x} + \Psi_{22} x^T x \right) dt \geq 0
\]

(7)

with 0 state initial conditions. Here the matrix \( \Psi \) represents different frequency ranges as:

\[
\begin{array}{c|c|c}
\Omega & |\omega| < \omega_m & |\omega| > \omega_h \\
\hline
\Psi & \begin{bmatrix} -1 & 0 \\ 0 & \omega_m^2 \end{bmatrix} & \begin{bmatrix} 1 & 0 \\ 0 & \omega_h^2 \end{bmatrix} \\
\end{array}
\]

where \( \omega_m = (\omega + \bar{\omega})/2 \). More specifically the following lemma is proved in (Sun et al., 2013).

Lemma 2.1. Consider the LPV system given by (1). Let

\[
\Pi = \begin{bmatrix} -I & 0 \\ 0 & \beta^2 I \end{bmatrix} \in \mathbb{R}^{(n_x+n_u) \times (n_x+n_u)}.
\]

Assume that (1) is asymptotically stable, and there exists \( \beta \geq 0 \) and \( \Psi \in \mathcal{H}_2 \). If there exists \( P_c(\rho) \), \( Q \in \mathcal{H}_2 \) such that \( Q > 0 \) and

\[
\begin{bmatrix} A(\rho) & B(\rho) \\ 0 & I \end{bmatrix}^T \begin{bmatrix} \Psi_{11} & \Psi_{12} \\ \Psi_{21} & \Psi_{22} \end{bmatrix} \begin{bmatrix} A(\rho) & B(\rho) \\ 0 & I \end{bmatrix} + \begin{bmatrix} C(\rho) & D(\rho) \end{bmatrix} \begin{bmatrix} C(\rho) & D(\rho) \end{bmatrix}^T < 0
\]

(8)

holds for all \( \rho \in \mathcal{F}_P^\rho \), then \( ||G(\rho)||_{\mathcal{H}_\infty} \geq \beta \) to a restricted class of input signals specified by (7) with \( x(0) = 0 \).

In the rest of the paper we will use the middle frequency formulation, and apply the following notation:

\[
\Xi = \begin{bmatrix}
\Psi_{11} & P_c(\rho) + \Psi_{12} Q \\
\Psi_{21} & P_c(\rho) + \Psi_{22} Q
\end{bmatrix}.
\]

(9)

Although stability of the LPV plant is assumed in the derivation of Lemma 2.1, it can be extended and used for unstable systems also. In this case, a stabilizing solution of the parameter-dependent Riccati Inequality is used for computing the minimal sensitivity (see Liu et al. (2005)).

2.3 Maximum sensitivity

The second mathematical tool that we use in the paper is the maximum sensitivity, the induced \( \mathcal{L}_2 \) norm of LPV systems. The definition reads as:

\[
\sup_{\rho \in \mathcal{F}_P^\rho} \sup_{||u||_2 \neq 0} \frac{||y||_2}{||u||_2} < \gamma,
\]

(10)

which can be efficiently computed using the Bounded Real Lemma for LPV systems.

Lemma 2.2. Given the LPV system in (1). If there exists a matrix function \( P_c(\rho) > 0 \) and a positive scalar \( \gamma \) such that (11) is satisfied for all \( \rho \in \mathcal{F}_P^\rho \), then \( ||G(\rho)||_2 \leq \gamma \) iff

\[
\begin{bmatrix}
P_{d}(\rho) A(\rho) + \gamma C^T(\rho) C(\rho) + \tilde{P}_{d}(\rho) \\
P_{d}(\rho) B(\rho) + D^T(\rho) C(\rho) \end{bmatrix}
\begin{bmatrix}
A(\rho) + \tilde{A}(\rho) D^T(\rho) P_{d}(\rho) \\
B(\rho) + D^T(\rho) P_{d}(\rho)
\end{bmatrix}
\begin{bmatrix}
P_{d}(\rho) A(\rho) + \gamma C^T(\rho) C(\rho) + \tilde{P}_{d}(\rho) \\
P_{d}(\rho) B(\rho) + D^T(\rho) C(\rho) \end{bmatrix}^T < 0
\]

(11)

where \( \gamma = \gamma^T \gamma \) and \( \tilde{P}_{d}(\rho) \) is a placeholder for the transpose of the symmetric off-diagonal term.
For this purpose we introduce to the subsystem to be decoupled, sensitivity through possible the control of the environment denoted by the dashed frame, which makes decoupling problem (see Figure 1). The goal is to create the activities for LPV systems, we are in the position to state the constraints over the selected LPV mode, while minimizes the impact on the one(s) to be decoupled. In this step only the state dynamics are considered, and the measurement equations are removed from the model equations. The concept is shown in Figure 2.

Before going into the details a side note has to be taken. It follows from the definition of the $H_\infty$ index and the $L_2$ gain that:

$$||G_c(\rho)||_{[\omega,\bar{\omega}]} = ||G_c^*(\rho)||_{[\omega,\bar{\omega}]}$$

where $*$ represents the conjugate system. In other words, the minimum sensitivity and the induced $L_2$ norm of the system and its conjugate is the same. As it will be seen next, using the conjugate representation assures the linearity in the design process.

If one writes the LMI constraints of (8) and (11) for the dual system then expresses the formulas in terms of the original representation, one gets (15) and (16), where

$$\Pi = \begin{bmatrix} -K_u(\rho) & 0 \\ 0 & \beta^2 I \end{bmatrix}.$$  

Here we have introduced the new parameter dependent matrix variable $K_u(\rho) = k_u(\rho) \cdot k_u(\rho)^T \in \mathbb{R}^{n_u \times n_u}$, as the dyadic product of the parameter-dependent input blend vectors.

It should be clear that the $K_u(\rho)$ terms are appearing in the matrix inequalities only because of the conjugate representation, otherwise we would be facing a bilinear (and quadratic) matrix problem, i.e. the conjugate form ensures linearity, while preserves the corresponding sensitivity values.

At the same time, the newly introduced variable $K_u(\rho)$ has rank 1 for all $\rho \in \mathcal{P}_Y$, which has to be taken into consideration in the solution. Hence, the input blend calculation is summarized in Proposition 4.1.

**Proposition 4.1.** The optimal $k_u(\rho)$ input blend for the system given in the form of (1) can be calculated as the left parameter dependent singular vector corresponding to the largest singular value of the $K_u(\rho)$ blend matrix, where $K_u(\rho)$ satisfies the following optimization problem.
Proposition 4.1 is a multi-objective optimization problem, which is frequent in mixed $H_2/H_\infty$ fault detection observer design (see e.g. Wei and Verhaegen (2008)). Since $K_u(\rho)$ is a parameter dependent matrix, $k_u(\rho)$ can be calculated through an analytic singular value decomposition (Mehrmann and Rath, 1993), which takes into account the parameter dependency and ensures continuity. However, concerning the rank constraint, some further remarks are required. The rank($K_u$) = 1 constraint in an earlier LTI version of the algorithm has been satisfied by a rank minimization heuristic. In practice this means the incorporation of the trace($K_u$) term in the objective function of (17). For further details see (Baar and Luspay, 2019). At the same time, this approach doesn’t guarantee the satisfaction of the rank constraint and was found to be numerically sensitive.

Therefore, in the present paper we apply a more systematic approach for the solution of Proposition 4.1 and handling the arising rank constraint. More precisely we use an alternating projection scheme extended to parameter dependent matrices.

The main idea was taken and tailored from (Grigoriadis and Beran, 2000), where the authors used an alternating projection technique for satisfying a coupling rank constraint in a fixed-order $H_\infty$ control design problem. For the solution of the present problem, the basic idea is the following. Let us denote with $\Gamma_{\text{conv}}$ the convex set which is formed by the LMIs (15) and (16) without the rank constraint on the $K_u(\rho)$ blend matrix. Denote this non-convex rank constraint on $K_u(\rho)$ by the set $\Gamma_{\text{rank}}$. Suppose that the sets have a nonempty intersection, and one wishes to solve the problem by finding a matrix function in the intersection: fulfilling both convex and non-convex constraints. The classical alternating projection scheme states that this problem can be solved by a sequence of orthogonal projections from one set to the other. Each step assures that the projected matrix in the corresponding set has the smallest distance from the one which was projected. The orthogonal projection theorem also assures that each projection is unique (Luenberger, 1997). However, even if the intersection exists, global convergence cannot be guaranteed in our case, due to the non-convex $\Gamma_{\text{rank}}$ set. Nevertheless local convergence of the proposed algorithm to a matrix which satisfies the above constraints is guaranteed (Grigoriadis and Beran, 2000).

The approach consists of various sequences of alternating projections. In each sequence the rank of the solution is reduced by one (starting from $n_u$, until rank($K_u(\rho)$) = 1 is achieved. The process of a single projection sequence is illustrated in Figure 3. Next the solution of Proposition 4.1 based on an alternating projection algorithm is presented in details. For this we borrow the following two lemmas from (Grigoriadis and Beran, 2000), and extend them to parameter dependent matrices. 

\[ \begin{align*}
\text{minimize} & \quad P_u(\rho), K_u(\rho), P_c(\rho), Q, \beta^2, \gamma^2 \\
\text{subject to} & \quad (15), (16), \quad 0 \preceq K_u(\rho) \preceq I, \\
\text{and rank} (K_u(\rho)) = 1, \quad \forall \rho \in \mathbb{F}_\rho^n
\end{align*} \]

with $I$ being the identity matrix with appropriate dimensions.

\[ \begin{align*}
\text{Lemma 4.2.} \quad & \text{Orthogonal projection to a lower dimensional set. Let } Z(\rho) \in \Gamma_{\text{rank}}^{n \times n} \text{ and let } Z(\rho) = U(\rho)S(\rho)V^T(\rho) \text{ be a parameter dependent singular value decomposition of } Z(\rho), \text{ calculated according to (Mehrmann and Rath, 1993). The orthogonal projection, } Z^*(\rho) = \text{Proj}_{\Gamma_{\text{rank}}} Z(\rho), \text{ of } Z(\rho) \text{ onto the } \Gamma_{\text{rank}}^{n-k \times n-k} \text{ dimensional set is given by } \\
& Z^*(\rho) = U(\rho)S_{n-k}(\rho)V^T(\rho), \quad (18)
\end{align*} \]

where the $S_{n-k}(\rho)$ diagonal matrix function is obtained by replacing the smallest $k$ singular value functions by zeros.

Note that the analytic SVD ensures the continuity of the blend vector, in contrast with local solutions. This feature is important from an implementation perspective.

\[ \begin{align*}
\text{Lemma 4.3.} \quad & \text{Projection to a general LMI constraint set } \Gamma. \text{ Let } \Gamma \text{ be a convex set, described by an LMI. Then the projection } X^*(\rho) = \text{Proj}_{\Gamma}(\rho)X(\rho) \text{ can be computed as the unique solution } Y(\rho) \text{ to the semidefinite programing problem } \\
& \min \text{ trace}(S(\rho)), \\
& \text{subject to } \begin{bmatrix} S(\rho) & Y(\rho) - X(\rho) \\ X(\rho)^T & I \end{bmatrix} \succeq 0, \\
& Y(\rho) \in \Gamma, \quad S(\rho), Y(\rho), X(\rho) \in \mathbb{R}^{n \times n}, \\
& \text{with } S(\rho) = S^T(\rho), \quad \forall \rho \in \mathbb{F}_\rho^n.
\end{align*} \]

\[ \begin{align*}
\text{4.2 Input blend calculation algorithm}
\end{align*} \]

Now we are in the position to present the numerical algorithm to Proposition 4.1. We are using a grid based solution of the problem. LMIs (15), (16) are written as a group of LMIs, with continuously differentiable functions $P_u(p)$ and $P_d(p)$ evaluated over the finite grid, leading to a finite dimensional convex problem. The following algorithm summarizes the input blend calculation.
**Algorithm 1: Input blend calculation with alternating projection**

1. The subsystems \( \hat{G}_c \) and \( \hat{G}_d \) are given in the form as shown in Figure 2.
2. A \( \beta \) iteration is carried out in order to find the largest value of \( \beta \) for which the following optimization problem can be solved without rank constraint.

\[
\min_{P_c(\rho), K_c(\rho), P_d(\rho), Q, \beta^2, \gamma^2} - \beta^2 + \gamma^2 + \text{trace}(K_u(\rho)) \\
\text{subject to (21), (20), } 0 \leq K_u(\rho) \preceq I, \ \forall \rho \in \mathcal{F}_p^2.
\] (22)

Set the counter variable to \( k = 1 \)

3. Alternating projection. Once reached, this point is iterated till convergence is achieved by a suitable selected error metric. The previously obtained values of \( \beta \) and \( \gamma \) are kept constant during the iteration, which consists of two steps.

a. Project \( K_u(\rho) \) to an \( n_n - k \) dimensional subset by Lemma 4.2 to obtain \( K_u^k(\rho) \).

b. Project the achieved reduced rank \( K_u^k(\rho) \) to the LMI constraint set by the following optimization problem

\[
\min_{P_c(\rho), K_c(\rho), P_d(\rho), Q, S(\rho)} \text{trace}(S(\rho)) \\
\text{s.t.: (21), (20), } 0 \leq K_u(\rho) \preceq I, \ Q \succeq 0, \\
\begin{bmatrix}
S(\rho) & K_u(\rho) - K_u^k(\rho) \\
K_u(\rho) - K_u^k(\rho) & I
\end{bmatrix} \succeq 0 \ \forall \rho \in \mathcal{F}_p^2.
\]

4. Set \( k = k + 1 \) and return to step 3, until rank 1 is achieved, then go to step 5.

5. Project \( K_u(\rho) \) to an \( n_n - k \) dimensional subset by Lemma 4.2. The results is \( K_u^k(\rho) \).

6. Calculate \( k_u(\rho) \) as the singular vector corresponding to the largest singular value in the parameter dependent Singular Value Decomposition of \( K_u^k(\rho) \).

Once \( k_u(\rho) \) is found, it is applied to the subsystems to give

\[
\begin{align*}
\dot{x}_{(c,d)}(t) &= A_{(c,d)}(\rho)x_{(c,d)}(t) + B_{(c,d)}(\rho)k_u(\rho)\bar{u}(t), \\
y_{(c,d)}(t) &= C_{(c,d)}(\rho)x_{(c,d)}(t) + D(\rho)k_u(\rho)\bar{u}(t),
\end{align*}
\] (23)

In the following we use the notation \( A_{(c,d)}(\rho) = A_{(c,d)}(\rho) \), \( B_{(c,d)}(\rho) = B_{(c,d)}(\rho)k_u(\rho) \), \( C_{(c,d)}(\rho) = C_{(c,d)}(\rho) \), \( D(\rho) = D(\rho)k_u(\rho) \) for the input-blended representation and discuss the corresponding output blend computation.

4.3 Output blend calculation

The output blend will maximize the information of the mode to be controlled to the single output, while it suppresses the effects of the undesired dynamics. The blend calculation process is shown in Figure 4. The direct feedthrough was not involved in the input blend calculation and so is neglected here. Its effect can be corrected by a \( k_y(\rho)^T D(\rho)k_u(\rho) \) feedforward term from \( \bar{u} \) to \( \bar{y} \) once

\[
\begin{bmatrix}
P_d(\rho)A_d(\rho) + A_d^T(\rho)P_d(\rho) + C_d^T(\rho)C_d(\rho) + \sum_{i=1}^{n_n} \frac{\partial P_d(\rho)}{\partial P_i} P_d(\rho)B_d(\rho) \\
B_d^T(\rho)P_d(\rho) \\
A_c(\rho)B_c(\rho) \end{bmatrix}
\begin{bmatrix}
\Psi_1Q & P_c(\rho) + \Psi_2Q & P_2(\rho) + \Psi_2Q \pm \frac{\partial P_2(\rho)}{\partial P_i}
\end{bmatrix}
\begin{bmatrix}
A_c(\rho)B_c(\rho) \end{bmatrix} \preceq 0
\] (20)

\[
\begin{bmatrix}
A_c(\rho)B_c(\rho) \\
0
\end{bmatrix}^T \mathcal{P} \begin{bmatrix}
A_c(\rho)B_c(\rho) \\
0
\end{bmatrix} \preceq 0
\] (21)

Fig. 4. Problem layout for output blend calculation

The output blend is found, according to the following proposition.

**Proposition 4.4.** The optimal \( k_u(\rho) \) output blend for the system given in the form of (23) can be calculated as the left parameter dependent singular vector corresponding to the largest singular value of the \( K_u(\rho) \) blend matrix, where \( K_y(\rho) \) satisfies the following optimization problem

\[
\min_{P_c(\rho), K_c(\rho), P_d(\rho), Q, \beta^2, \gamma^2} - \beta^2 + \gamma^2 \\
\text{subject to (25), (26), } 0 \leq K_u(\rho) \preceq I, \quad \text{and rank}(K_y(\rho)) = 1, \ \forall \rho \in \mathcal{F}_p^2
\] (24)

with \( I \) being the identity matrix with appropriate dimensions, and \( \mathcal{P} = \begin{bmatrix} -K_y(\rho) & 0 \\ 0 & \beta^2I \end{bmatrix} \).

The solution of Proposition 4.4 leads to a very similar calculation as Algorithm 1.

5. NUMERICAL RESULTS

The presented algorithm was tested on a flexible winged aircraft model, which has been developed in the FLEXOP project (Consortium et al., 2015). The aircraft is equipped with eight ailerons (four on the left and four on the right wings) and two rudders on each side. Measurements are given at the 90% spanwise location on the left and right trailing edge, providing information about the vertical acceleration (\( a_z \)) and the angular rates (\( \omega_x, \omega_y \)) around the lateral and longitudinal axis of the aircraft respectively.

The model has 5 standard aircraft rigid body modes, and two additional flutter modes arising from the coupling of the aerodynamic and structural forces. These flutter modes are responsible for the oscillatory motions of the wing, and they are becoming unstable over a certain airspeed. Further details of the modeling can be found in Luspay et al. (2018b). An LPV model was created based on the nonlinear one by trimming and linearization, and the indicated airspeed was selected as the scheduling parameter (\( \rho \)). The modal form given in (3) was achieved by applying the algorithm of Luspay et al. (2018a), which was followed by a parameter varying model order reduction.
The obtained low order LPV model is used for illustrating the proposed decoupling methodology.

In our example we aim to decouple the rigid body dynamics of the aircraft from the asymmetric flutter mode over the \( \rho = [45, 56] \) airspeed range. This would assure that a controller designed for the asymmetric flutter mode, will not interact with the rigid body modes and the the corresponding baseline controller. To achieve this the computation of a continuous \( k_u(\rho) \) and \( k_y(\rho) \) blend vector functions is required. For the parameter-dependent solution a quadratic basis function was selected for the i.e.: \( P_{(c,d)}(\rho) = P_0 + P_1 \rho + P_2 \rho^2 \). The parameter dependence of the \( K_u(\rho) \) and \( K_y(\rho) \) blend matrix functions were selected to be linear. The value of \( \dot{\rho} \) represents the longitudinal acceleration of the aircraft, and its maximum value was selected to be half of the gravitational acceleration. The LPV theory then assures that the decoupling is achieved when the airspeed is in the designed range, it is changing according to the prescribed basis functions, and \( \dot{\rho} \leq \rho \leq \ddot{\rho} \).

Figure 5 shows the maximal singular values for the subsystems to be controlled and decoupled at various airspeed values. After solving the blending problem as described in Section 4 the \( k_u(\rho) \) and \( k_y(\rho) \) blending vector functions were successfully determined and applied to the system. It is possible to evaluate these blending functions at certain airspeed values (frozen parameter): this results in a family of singular value plots corresponding to the subsystems. This is shown in the lower part in Figure 5. It is obvious that before blending the two subsystems are coupled, while by suitable blending functions it was possible to decouple them.

However time domain simulations are also needed in order to evaluate the decoupling performance when the system is in transition between grid points. In the following example a single step input (\( \bar{u} = 1(t) \)) has been applied to the blended subsystems, while the scheduling parameter has been varying as \( \rho(t) = \sin(\omega t) \) with \( \omega \) which satisfies conditions on \( \dot{\rho} \) used throughout the design. The responses of the two blended subsystems can be seen in the lower subfigure of Figure 6. Clearly by the application of the input and output blends, the asymmetric flutter mode is excited on a much higher level than the rigid body modes, and so a suitably designed controller will interact with this mode only.

Finally, the calculated blending functions are continuous and smooth functions of the parameter (\( \rho \)) and their evolution is plotted in the upper subfigure of Figure 6.

6. SUMMARY

A method for individual control of a selected subsystem was presented for LPV systems. It relies on suitably designed input and output blend vector functions, which are transforming the underlying MIMO plant into a SISO one. If the selected subsystem is controlled through the transformed input and output, then the corresponding controller will not interact with the other subsystems in the plant. The advantage of the presented method is that, it does not introduce further dynamics into the system. The blend vector functions are designed based on LMI techniques borrowed from the robust control literature. The minimum sensitivity (denoted by the \( \mathcal{H}_\infty \) index) is maximized for the subsystem to be controlled, while the \( \mathcal{H}_\infty \) norm of the remaining dynamics is minimized. In the LPV framework the problem is solved over a finite grid. The effectiveness of the method has been validated by a time domain simulation of a flexible wing aircraft. The flexible subsystem was successfully decoupled from the rigid body modes. The authors also have the intention to
incorporate the effects of model uncertainties to the blend vector calculations in the near future.

ACKNOWLEDGEMENTS

The research leading to these results is part of the FLEXOP project. This project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement No 636307. This paper was supported by the Janos Bolyai Research Scholarship of the Hungarian Academy of Sciences. The research reported in this paper was supported by the Higher Education Excellence Program of the Ministry of Human Capacities in the frame of Artificial Intelligence research area of Budapest University of Technology and Economics (BME FIKPMI/FM).
