Mg²⁺ is an essential mineral with pleotropic impacts on cellular physiology and functions. It acts as a cofactor of several important enzymes, as a regulator of ion channels such as voltage-dependent Ca²⁺ channels and K⁺ channels and on Ca²⁺-binding proteins. In general, Mg²⁺ is considered as the main intracellular antagonist of Ca²⁺, which is an essential secondary messenger initiating or regulating a great number of cellular functions. This review examines the effects of Mg²⁺ on mitochondrial functions with a particular focus on energy metabolism, mitochondrial Ca²⁺ handling, and apoptosis.

1. Impact of Mg²⁺ on Cellular Functions and Intracellular Mg²⁺ Dynamics

Mg²⁺ is an essential mineral with pleotropic impacts on cellular physiology and functions [1, 2]. It acts as a cofactor of several important enzymes, especially those requiring ATP in order to be fully functional, such as the various protein kinases, proteins involved in nucleic acid metabolism, or ATPases involved in the transport of various ions [1, 2]. In addition, Mg²⁺ alters the electrophysiological properties of ion channels such as voltage-dependent Ca²⁺ channels and K⁺ channels [3]. The voltage-dependent block of N-methyl-D-aspartate receptor by Mg²⁺ [4, 5] represents an important phenomenon in the neurosciences. Finally, Mg²⁺ can affect the binding affinity of Ca²⁺ to specific Ca²⁺-binding proteins, such as calmodulin [6], S100 [7], troponin C [8], and parvalbumin [9, 10]. The effects of Mg²⁺ on Ca²⁺-handling proteins are responsible for the significant modification of intracellular Ca²⁺ dynamics and signalling [11]. In general, Mg²⁺ is considered as the main intracellular antagonist of Ca²⁺, which is an essential secondary messenger initiating or regulating a great number of cellular functions in various cells [12].

Recent progress in the field of Mg²⁺ transporter research has led to the identification of plasma membrane Mg²⁺ transporter SLC41A1 [13, 14], mitochondrial Mg²⁺ efflux system SLC41A3 [15], mitochondrial Mg²⁺ influx channel Mrs2 [16], and a mitochondrial Mg²⁺ exporter [17]. Substantial progress has also been achieved with respect to the regulation of whole body Mg²⁺ homeostasis [18]. These discoveries have shed new light on the importance of Mg²⁺ in cellular physiology including mitochondrial functions. Mitochondria have been demonstrated to be capable of both the accumulation of Mg²⁺ and the release of Mg²⁺ [19, 20]. Thus, mitochondria represent an important intracellular Mg²⁺ store. Significant amount of intracellular Mg²⁺ has also been shown to be localised within the lumen of the endoplasmic/sarcoplasmic reticulum (ER/SR) [21]. However, unlike mitochondria, the molecular mechanisms of Mg²⁺ transport through the ER membrane are not yet clear. Since impact of Mg²⁺ on cellular functions was summarised in recent reviews [1–3], we will deal, in this review, with the effects of Mg²⁺ on mitochondrial functions with a particular focus on energy metabolism, mitochondrial Ca²⁺ handling, and apoptosis (Figure 1).

2. Impact of Mg²⁺ on Energy (Oxidative) Metabolism

The oxidation of coenzymes (reduced in glycolysis, reaction catalysed by pyruvate dehydrogenase complex, β oxidation, and Krebs cycle) in the mitochondrial respiratory chain and
the consequent mitochondrial oxidative phosphorylation represent the major pathway of intracellular energy production in the form of ATP for all mammalian cells, except for erythrocytes. A small fraction of ATP is produced in the cytoplasm by the oxidation of glucose in the glycolysis pathway. Many of the glycolytic enzymes (hexokinase, phosphofructokinase, phosphoglycerate kinase, and pyruvate kinase) have previously been shown to be sensitive to Mg$^{2+}$. The most important effect is attributable to the MgATP$_2$ complex, which is a cofactor for these enzymes, whereas other chelation forms are inactive or inhibitory [22].

The study of the impact of Mg$^{2+}$ on the enzymes of energy metabolism in mitochondria began several decades ago [23, 24]. The earlier approach, which was focused on the description of the Mg$^{2+}$ effect on isolated mitochondrial enzymes [25, 26], has subsequently been substituted by studies focused on the effect of Mg$^{2+}$ on energy metabolism in isolated vital mitochondria [27–29] or vital cells [30, 31]. Some results obtained by the kinetic analysis of isolated enzymes have also been further analysed in more details by mathematical methods [32, 33]. Mg$^{2+}$ has been documented to enhance the activity of three important mitochondrial dehydrogenases involved in energy metabolism. Whereas activities of isocitrate dehydrogenase (IDH) and 2-oxoglutarate dehydrogenase complex (OGDH) are stimulated directly by the Mg$^{2+}$-isocitrate complex [25] and free Mg$^{2+}$ [34], respectively, the activity of pyruvate dehydrogenase complex (PDH) is stimulated indirectly via the stimulatory effect of Mg$^{2+}$ on pyruvate dehydrogenase phosphatase, which dephosphorylates and thus activates the pyruvate decarboxylase of PDH [35]. OGDH is the rate-limiting enzyme of the Krebs cycle and acts as an important mitochondrial redox sensor [36, 37]. The results obtained by the complex investigation of the impact of Mg$^{2+}$ on ATP synthesis, the mitochondrial transmembrane potential, and respiration indicate that OGDH is the main step of oxidative phosphorylation modulated by Mg$^{2+}$ when 2-oxoglutarate is the oxidisable substrate; with succinate, the ATP synthase is the Mg$^{2+}$-sensitive step [29]. Indeed, Mg$^{2+}$ has been shown to be the activator of ATP synthesis by mitochondrial F$_{0}$/F$_{1}$-ATPase [38, 39].

**Figure 1**: Regulation of mitochondrial functions by Mg$^{2+}$. Mitochondrial Mg$^{2+}$ activates (———→) three dehydrogenases in the mitochondrial matrix: pyruvate dehydrogenase (conversion of mitochondrial pyruvate to acetyl coenzyme A), isocitrate dehydrogenase (conversion of isocitrate to 2-oxoglutarate), and 2-oxoglutarate dehydrogenase (conversion of 2-oxoglutarate to succinyl coenzyme A). In addition, mitochondrial Mg$^{2+}$ activates F$_{0}$/F$_{1}$-ATP synthase, which is the terminal complex of mitochondrial oxidative phosphorylation (OXPHOS). This regulatory activity contributes to mitochondrial energy metabolism. Mitochondrial Mg$^{2+}$ inhibits (— | ——) Ca$^{2+}$ transporters localised in the inner mitochondrial membrane: Ca$^{2+}$-dependent permeability transition pore (PTP) opening that results in the release of a variety of compounds from mitochondria including Ca$^{2+}$, mitochondrial Ca$^{2+}$ uniporter (MCU), mitochondrial ryanodine receptor (RyR), and mitochondrial Na$^{+}$/Ca$^{2+}$ exchanger (NCX). This regulatory activity contributes to both intracellular and mitochondrial Ca$^{2+}$ homeostasis. Cytoplasmic Mg$^{2+}$ regulates mitochondrial Bax/Bak-dependent apoptosis, which is regulated by proteins of the Bcl-2 family such as Bcl-X$_{L}$, Bcl-2. TCA: tricarboxylic acid cycle/Krebs cycle, ACoA: acetyl coenzyme A, C: citrate, IC: isocitrate, OG: 2-oxoglutarate, SC: succinyl coenzyme A, S: succinate, F: fumarate, M: malate, OA: oxaloacetate, RaM: rapid mode of mitochondrial Ca$^{2+}$ uptake, HCX: mitochondrial H$^{+}$/Ca$^{2+}$ exchanger, SLC41A3: mitochondrial Mg$^{2+}$ influx system, Mrs2: mitochondrial Mg$^{2+}$ influx channel, VDAC: voltage dependent anion channel.
Taken together, the data suggest that Mg2+ has significant impact on the metabolic state, which is mediated by its stimulatory effect on the above-mentioned mitochondrial enzymes. However, the mitochondrial metabolic state seems, in turn, to affect the Mg2+ concentration of both the matrix [40] and the cytoplasm [41]. Finally, the effect of Mg2+ on energy metabolism partially interferes with the stimulatory effect of Ca2+ on energy metabolism and mitochondrial Ca2+ transport that are particularly important in excitable cells such as neurons [42, 43] and muscle cells [44]. Increase of extramitochondrial concentration of Mg2+ that was not associated with increase of Mg2+ in mitochondrial matrix led in the presence of Ca2+ to the attenuation of state 3 respiration and stimulation of state 4 respiration [45]. This effect was attributed to the Mg2+-dependent inhibition of mitochondrial Ca2+ uptake (see further) that resulted in decrease of matrix Ca2+ concentration [45].

3. Involvement of Mg2+ in Regulation of Mitochondrial Ca2+ Transport

Mitochondria are important players in intracellular Ca2+ homeostasis and signalling [46, 47]. In response to specific signals, mitochondria are capable of both the active accumulation of intracellular Ca2+ and the release of Ca2+ from mitochondria via different Ca2+ transport mechanisms localised on mitochondrial membranes (Figure 1). Thus, they are considered as rapid-uptake slow-release buffers of cytosolic Ca2+ [48, 49]. In addition to cell signalling, mitochondrial Ca2+ plays an important role with respect to metabolism and cell survival [50, 51]. Several molecular mechanisms control mitochondrial Ca2+ transport [52].

The transport of Ca2+ through the outer mitochondrial membrane (OMM) is mediated via voltage-dependent anion channel (VDAC) that can be modulated in various ways [52], but little is known about the effect of Mg2+ on VDAC-dependent Ca2+ transport. An early study had shown that Mg2+ did not alter single channel activity but modified single current amplitudes in the lower conductance channel [53].

Active mitochondrial Ca2+ uptake is mediated by a specific transporter, namely the mitochondrial Ca2+ uniporter (MCU), which transfers Ca2+ through the inner mitochondrial membrane (IMM) at the expense of the proton gradient generated by the mitochondrial respiratory chain. The rate of uptake has been described to be proportional to the mitochondrial transmembrane potential [54], but, recently, the exponential dependence of the relative Ca2+ transport velocity on the mitochondrial transmembrane potential has received greater support [55, 56]. Another physiologically important question is associated with the low affinity of MCU for Ca2+ (apparent \( K_d = 20-30 \mu M \) at 1 mM Mg2+) [57]. The discrepancy between the low Ca2+ affinity of the MCU observed in vitro and the high efficiency observed in vivo has been explained on the basis of the microheterogeneity of cytoplasmic Ca2+ rising during stimulation. The microdomains of high intracellular Ca2+ concentration (10–20 \( \mu M \)) have been suggested to be transiently formed in regions of close proximity to mitochondria and Ca2+ channels of the ER or of the plasma membrane [58]. MCU-mediated Ca2+ transport in isolated heart, kidney, and liver mitochondria is inhibited in the presence of 1.5 mM Mg2+ by approximately 50% in the heart and kidney and by 20% in the liver [59]. Similarly, the inwardly rectifying mitochondrial Ca2+ current displaying sensitivity to ruthenium red and selectivity to divalent cations, similar to that of MCU, is reduced by 0.5 mM of cytoplasmic Mg2+ concentration to 41% of its conductance in Mg2+-free solutions [60]. Moreover, mitochondrial Mg2+ loading has been shown to suppress MCU Ca2+-uptake rates [61]. The data of experimental studies were used for mathematical modeling of MCU-mediated Ca2+ transport suggesting a mixed-type inhibition mechanism for Mg2+ inhibition of the MCU function [62]. On the contrary, Mg2+ increased the rate of the active and ruthenium-red-sensitive accumulation of Ca2+ by isolated rat heart mitochondria [63]. The discrepancy has been attributed to the contribution of Ca2+ used for measurements. In the last-mentioned study [63], Ca2+ uptake was measured at 25 \( \mu M \) Ca2+, thus at a concentration that in the absence of Mg2+ is enough to open the permeability transition pore (PTP). Although the rate of Ca2+ transport mediated by MCU is inhibited by Mg2+, the net accumulation of Ca2+ in mitochondria was increased because of the Mg2+-mediated prevention of Ca2+ leakage from mitochondria via PTP.

Some controversial findings have been reported to be related to the mitochondrial accumulation of Ca2+ through IMM via the mitochondrial ryanodine receptor (mRyR). Western blot analysis, immunogold electron microscopy, and the high-affinity binding of [3H]-ryanodine indicate that a low level of mRyR is localised within IMM [64]. Similarly to MCU, mRyR is inhibited by low concentrations of ruthenium red (1–5 \( \mu M \)) and by Mg2+ [64]. However, the IMM localisation of RyRs by immunogold labelling has not been confirmed by another group [65]. Results obtained in our laboratory also argue against the significant physiological importance of mitochondrial Ca2+ uptake via mRyR, since only energised rat heart mitochondria are able to accumulate substantial amounts of Ca2+ and the accumulation is prevented by the submicromolar concentration of ruthenium red [63]. Finally, the group of Sheu [66] has suggested that, upon Ca2+ overload in the matrix, mRyR might be responsible for mitochondrial Ca2+ efflux, thus preventing the activation of PTP (see below).

Recent study documented that Mg2+ does not affect the rapid mode of mitochondrial Ca2+ uptake [67] that represents another mechanism of Ca2+ transport through the IMM distinct from MCU [68].

The main route of mitochondrial Ca2+ release has previously been demonstrated to depend on the Ca2+-induced release of Ca2+ from mitochondria (mCICR). The mechanism of mCICR involves the transitory opening of the PTP operating in a low conductance mode. Therefore, Ca2+ fluxes from mitochondria are a direct consequence of the mitochondrial depolarisation spike (mDPs) caused by PTP opening [69]. In vitro, both mDPS and mCICR can propagate from one mitochondrion to another, generating travelling depolarisation and Ca2+ waves. Mitochondria therefore appear to be excitable organelles capable of...
generating and conveying electrical and \( \text{Ca}^{2+} \) signals. In living cells, mDPS/mCICR is triggered by \( \text{IP}_3 \)-induced \( \text{Ca}^{2+} \) mobilisation leading to amplification of the \( \text{Ca}^{2+} \) signals primarily emitted from the ER [69]. As documented in our laboratory, the opening of PTP in the low conductance mode depends significantly on the \( \text{Mg}^{2+} \) concentration [63]. This is in agreement with the previous study that documented the inhibitory effect of divalent cations including \( \text{Mg}^{2+} \) on \( \text{Ca}^{2+} \)-dependent opening of PTP [70].

Two additional antiporters are suggested to play an important role with respect to mitochondrial \( \text{Ca}^{2+} \) release/efflux [51, 57]. In nonexcitable tissues (liver, kidney), such an antiport, appear to be predominantly an \( \text{H}^+/\text{Ca}^{2+} \) exchanger, whereas in excitable tissues (heart, brain), it appears to be primarily a \( \text{Na}^+/\text{Ca}^{2+} \) exchanger [71, 72]. The molecule responsible for the \( \text{Na}^+/\text{Ca}^{2+} \) exchange was identified in 2010 [73]. A possible molecular candidate for the \( \text{H}^+/\text{Ca}^{2+} \) exchange (Letm1) was reported in 2009 [74], although this proposal is still controversial [75, 76]. As suggested by Takeuchi and coworkers [51], further analysis is necessary to determine whether Letm1 is, indeed, the \( \text{H}^+/\text{Ca}^{2+} \) exchanger mediating \( \text{Ca}^{2+} \) extrusion from mitochondria. The transport activity of the \( \text{Na}^+/\text{Ca}^{2+} \) exchanger is inhibited by \( \text{Mg}^{2+} \) at concentration 2.5 mM [77], whereas \( \text{Mg}^{2+} \) does not inhibit the \( \text{Ca}^{2+} \) flux mediated by the \( \text{H}^+/\text{Ca}^{2+} \) exchanger Letm1, even at ~300-fold excess [75].

4. \( \text{Mg}^{2+} \) and Mitochondrial Apoptosis

Mitochondria play an important role in the process of the intrinsic pathway of apoptosis [78, 79]. They are both targets of proteins of the Bcl-2 family that are essential regulators of the intrinsic apoptotic pathway initiation [79, 80], and the residence of proteins playing a crucial role in the execution of intrinsic apoptosis (cytochrome c, Smac/Diablo, apoptosis-inducing factor, and endonuclease G) [81]. In some cells, the extrinsic (receptor) pathway of apoptosis is connected to the intrinsic pathway via receptor-initiated cleavage of Bid protein, which is also a member of the Bcl-2 family, and the consequent translocation of truncated Bid (tBid) to the mitochondria [79, 81].

In contrast to the well-established role of \( \text{Ca}^{2+} \) in apoptosis [82], the role of \( \text{Mg}^{2+} \) has been largely ignored. Several in vitro studies have suggested the stimulatory role of \( \text{Mg}^{2+} \) in both the extrinsic and intrinsic pathways of apoptosis. Changes in cytosolic \( \text{Mg}^{2+} \) concentration have been observed in the glycodeoxycholate-induced apoptosis of hepatocytes [83], during the proanthocyanidin/doxorubicin-induced apoptosis in K562/DOX cells [84] and in the Fas ligand-induced apoptosis of B lymphocytes [85]. The elevation of intracellular \( \text{Mg}^{2+} \) observed in early phase of apoptosis has been explained by \( \text{Mg}^{2+} \) being necessary to stimulate the activity of \( \text{Ca}^{2+}/\text{Mg}^{2+} \)-dependent endonucleases, which are the executors of apoptosis. Patel et al. [83] have shown that the incubation of cells in \( \text{Mg}^{2+} \)-free medium prevents the rise in intracellular \( \text{Mg}^{2+} \) and reduces nuclear DNA fragmentation. On the contrary, Chien and coworkers [85] have documented that an increase in cytosolic free \( \text{Mg}^{2+} \) is independent of the extracellular \( \text{Mg}^{2+} \) concentration and the source of the elevated intracellular \( \text{Mg}^{2+} \) has been suggested to be in the mitochondria. This suggestion is supported by the discovery of mitochondrial \( \text{Mg}^{2+} \) influx and influx transporters [15, 16] and by experiments revealing the efflux of \( \text{Mg}^{2+} \) from mitochondria with preserved integrity (i.e., high transmembrane potential, no swelling) as the response to the apoptotic compound, gliotoxin [86]. Finally, the upregulation of Mrs2 has been shown to be responsible for the inhibition of the adriamycin-induced apoptosis of a gastric cancer cell line, probably by suppressing Bax-induced cytochrome c release from the mitochondria [87].

Previous studies have also documented the impact of \( \text{Mg}^{2+} \) on cytochrome c release from mitochondria, an event that is followed by apoptosome formation and further progression of mitochondrial apoptosis [79]. Although a promoting effect of \( \text{Mg}^{2+} \) has been suggested, the impact of \( \text{Mg}^{2+} \) on cytochrome c release seems to depend on the mechanism of OMM permeability increase. The release of both Bax- [90] and BID-induced cytochrome c [91] has been shown to be independent of the PTP pore but to be highly stimulated by \( \text{Mg}^{2+} \). On the contrary, Noxa-induced cytochrome c release is inhibited by \( \text{Mg}^{2+} \); this can be explained by the ability of \( \text{Mg}^{2+} \) to inhibit PTP [92], since PTP opening can result in the release of a variety of compounds from the mitochondria including that of cytochrome c leading to apoptosis [81].

5. Conclusions

Mitochondrial dysfunction has been implicated in the mechanisms of several serious human pathologies including metabolic [93, 94], cardiovascular [95], and neurodegenerative [96, 97] diseases. As we have discussed above, \( \text{Mg}^{2+} \) affects mitochondrial functions that have an important impact on cell survival. Recent work on Mrs2 knockdown HeLa cells has unambiguously revealed that the disruption of mitochondrial \( \text{Mg}^{2+} \) homeostasis has a dramatic impact on a cellular energy status and cell vulnerability [31]. Moreover, mitochondrial extruder SLC41A3 has been shown to be involved in the regulation of the whole-body \( \text{Mg}^{2+} \) balance [98]. These findings argue for more systematic research in the field of \( \text{Mg}^{2+} \) and mitochondria. Since mitochondria display significant cell and tissue heterogeneity [49, 99], the impact of mitochondrial \( \text{Mg}^{2+} \) on cellular physiology can also be anticipated to be cell- and tissue-type-dependent. Experiments on a variety of cell types will be important. In addition, the impact of \( \text{Mg}^{2+} \) on apoptosis initiation and execution in various cells has to be investigated in more detail. With respect to apoptosis, the cell-type specificity and the cause-consequence relations between apoptosis initiation and changes in the intracellular or mitochondrial concentration of \( \text{Mg}^{2+} \) are still unclear. Moreover, recent studies strongly point to the importance of ER-mitochondria interactions with respect to mitochondrial functions, \( \text{Ca}^{2+} \) homeostasis, and dynamics [100, 101]. Since the ER
transport of Mg\(^{2+}\) is not as clear yet, the study of the transport of Mg\(^{2+}\) through the ER membrane and the possible impact of the luminal Mg\(^{2+}\) concentration on ER-mitochondria crosstalk and on mitochondrial Mg\(^{2+}\) transport and functions will be crucial. Finally, other processes are localised in the mitochondria, which are also considered as the main site of the intracellular production of reactive oxygen species. The effect of Mg\(^{2+}\) on these processes has not been discussed in this review, but some interest should be focused on this direction in the future.
