(Received 10 October, 2014; Accepted 18 December, 2014)

Reactive oxygen species not only cause damage but also have a physiological role in the protection against pathogens and in cell signalling. Mitochondrial nutrients, such as coenzyme Q<sub>10</sub> and α-lipoic acid, beside their acknowledged antioxidant activities, show interesting features in relation to their redox state and consequent biological activity. In this study, we tested whether oral supplementation with 200 mg/day of coenzyme Q<sub>10</sub> alone or in association with 200 mg/die of α-lipoic acid for 15 days on 16 healthy subjects was able to modulate the oxidative status into different compartments (plasma and cells), in basal condition and following an oxidative insult in peripheral blood lymphocytes exposed in vitro to H<sub>2</sub>O<sub>2</sub>. Data have shown that tested compounds produced antioxidant and bioenergetic effects improving oxidative status of the lipid compartment and mitochondrial functionality in peripheral blood lymphocytes. Simultaneously, an increased intracellular reactive oxygen species level was observed, although they did not lead to enhanced DNA oxidative damage. Coenzyme Q<sub>10</sub> and α-lipoic acid produced beneficial effects also steering intracellular redox poise toward a pro-oxidant environment. In contrast with other antioxidant molecules, pro-oxidant activities of tested mitochondrial nutrients and consequent oxidant mediated signalling, could have important implications in promoting adaptive response to oxidative stress.

**Key Words:** Coenzyme Q<sub>10</sub>, α-lipoic acid, reactive oxygen species, mitochondrial functionality, DNA damage

An imbalance between oxidants and antioxidants in favour of the oxidants, potentially leading to damage, is termed “oxidative stress”. Oxidants are formed as a normal product of aerobic metabolism but can be produced at elevated rates under pathophysiological conditions. Reactive oxygen species (ROS) are chemically reactive molecules containing oxygen and they are generated as by-products during mitochondrial electron transport or during the defense process against infections. Moreover ROS are responsible for damage to biomolecules. In fact, many disease states are connected with ROS damage which is often associated with injury to bio-molecules, including carbohydrates, amino acids, fatty acids and nucleotides. These diseases include inflammations, infections, cancer, lifestyle-related diseases and metabolic diseases, such as diabetes mellitus, atherosclerosis and neurological disorders such as Alzheimer’s disease. However, free radicals not only cause damage but also have a physiological role in the protection against pathogens and in cell signalling. Differently from other signalling molecules, ROS to a large extent are chemically reactive and some of them extremely unstable in biological systems. The specificity of ROS signalling functions depends on their chemical reactivity and production system. ROS signalling process generally begins with an unstable primary ROS signal that is subsequently transformed into a more stable secondary signal. During this process, ubiquitous biological molecules (e.g., nucleic acids, nucleotides, lipids and reactive protein residues) serve as chemical sensors, which can effectively perceive ROS and are available in cells for a wide repertoire of reactions. In healthy aerobes, production of ROS is approximately balanced with antioxidant defense systems. The balance is not always perfect, however, so that some ROS-mediated damage occurs frequently. In order to preserve the proper oxidative balance in biological systems, the cell has several lines of endogenous antioxidant defenses. Moreover, antioxidant supplementation may contribute to sustain endogenous defenses promoting delaying of the aging process and prevention of age-associated diseases. Among these compounds, coenzyme Q<sub>10</sub> (CoQ<sub>10</sub>) and α-lipoic acid (LA) are active both as cellular antioxidants and mitochondrial nutrients. Coenzyme Q is a key component of the mitochondrial respiratory chain and it was initially mainly known for its role in oxidative phosphorylation; subsequently it was demonstrated its presence in other sub-cellular fractions and in plasma lipoproteins, where it acts as a lipophilic antioxidant. Lately modulatory effects of CoQ<sub>10</sub> on gene expression were also recognized. These three functions underlie the rationale for its use in clinical practice and as a food supplement. α-Lipoic acid is a naturally occurring dithiol compound synthesized enzymatically in the mitochondrion from octanoic acid. Just like CoQ<sub>10</sub>, α-lipoic acid is also involved both in energy metabolism and as an antioxidant. In fact, LA is a necessary cofactor for mitochondrial α-keto acid dehydrogenase and, for this reason, plays a critical role in mitochondrial energy metabolism. Moreover, its antioxidant function is associated with the reduced form, dihydro lipoic acid (DHLA), a powerful mitochondrial antioxidant. Furthermore, DHLA recycles other cellular antioxidants including CoQ<sub>10</sub> and vitamin C and is involved in iron and copper chelation. These mitochondrial nutrients, beside their acknowledged antioxidant activities, show interesting features in relation to their redox state and consequent biological activity. Linnane et al. proposed that CoQ<sub>10</sub>’s particular sub-cellular redox poise (ratio of ubiquinol to ubiquinone) represents a key determinant in regulating metabolic control function. Redox

poise variations of this molecule are able to locally influence redox status, resulting in a signaling process. This hypothesis is in agreement with recently developed concepts in the field of free radical research such as nucleophilic tone and para-hormesis. Forman et al.\(^{(1)}\) suggest the term nucleophilic tone to describe the cellular, tissue, organ, or even organism level of protection against electrophiles (including many free radicals and/or oxidants) by nucleophiles. This should be not only provided by antioxidators \textit{per se} but could be modulated by non-toxic compounds that maintain an adaptive defense system by mimicking electrophiles and increasing the nucleophilic tone. They propose the name para-hormesis to describe this adaptive hormetic-like response that does not necessarily require an activating or initiating stress, remembering that hormesis refers to the positive adaptation effects of low-dose toxins, toxicants, or other stressors.

In this context, the aim of the study was to test whether mitochondrial nutrients, CoQ\(_{10}\) and LA, were able to modulate the oxidative status into different compartments (plasma and cells) in basal condition and following an oxidative insult in peripheral blood lymphocytes (PBL) exposed \textit{in vitro} to H\(_2\)O\(_2\).

**Materials and Methods**

**Experimental design.** Sixteen healthy subjects (8 male/8 female), aged 26.8 ± 2.8 with BMI 23.6 ± 1.4 volunteered in this study. Use of any type of dietary supplement or fortified food in the previous 3 months was considered an exclusion criterion. All participants were instructed to continue their normal life style without modifying their usual physical activities. Volunteers were divided in two homogeneous treatment groups: one group integrated its diet with 200 mg/day CoQ\(_{10}\) alone, while the other one took 200 mg/day CoQ\(_{10}\) in association with 200 mg/day of LA. Food supplements were taken in two doses during lunch and dinner for two weeks. CoQ\(_{10}\) and LA were provided by Pharmanord (Copenhagen, Denmark).

Blood samples (12 ml) were withdrawn from fasting volunteers and collected in ethylenediaminetetraacetic acid (EDTA) and heparin vacutainers at the beginning and after the two weeks of treatment with CoQ\(_{10}\) alone or in association with LA. The evening before the second blood withdrawal the volunteers did not take any food supplements. The study was performed in accordance with the Helsinki Declaration of human studies in 2009. All participants signed an informed consent document.

**Plasma separation and lymphocyte isolation.** Blood collected in a heparinized vacutainer was centrifuged at 1,600 g for 10 min at 4°C to separate plasma, which was subsequently kept at −80°C until used for assessment of CoQ\(_{10}\) content. 8 ml of blood were collected in vacutainers containing EDTA, washed twice with Phosphate Buffered Saline (PBS) and immediately used for PBL isolation by density-gradient centrifugation on lymphoprep (Nyegaard, Oslo, Norway). Isolated cells were washed twice in PBS. Lymphocyte count was determined using a hemocytometer chamber and cells number was adjusted to 1.2 × 10\(^6\) cells/ml using RPMI medium (Sigma, Milan, Italy) pH 7.4 supplemented with 10% Fetal Bovine Serum (FBS) (Sigma, Milan, Italy).

**Cell damage after oxidative stress induction.** Lymphocyte samples (1.2 × 10\(^6\) cells/ml) were incubated in the dark for 4 h at 37°C in complete medium alone (control) or with 100 and 200 μM H\(_2\)O\(_2\) (Sigma).\(^{(13)}\) At the end of the incubation, an aliquot of counted cells was washed in PBS and stored at −80°C for subsequent cellular CoQ\(_{10}\) analysis and DNA damage assessment by comet assay. Cellular integrity for DNA analysis was ensured by using a cryopreservation medium.\(^{(14)}\) Flow cytometric investigations for the Mitochondrial Membrane Potential (MMP) and intracellular ROS levels were performed immediately.

**Plasma and cellular levels of CoQ\(_{10}\).** CoQ\(_{10}\) content and its oxidative status in plasma were assayed by High-Performance Liquid Chromatography (HPLC) with Electro-Chemical Detector (ECD) by Shiseido Co. Ltd. (Tokyo, Japan). Mobile phases were prepared as described,\(^{(15)}\) auto-sampler Model 3033, switch valve Model 3012, concentration column CQC and separation column CQS, pump one and two were Model 3001 (Shiseido Co. Ltd., Tokyo, Japan). The system is characterized by a post-separation reducing column (Shiseido CQR) capable of fully reducing the peak of ubiquinone. The oxidation potential for ECD was 650 mV. Plasma and cellular oxidative status were expressed as percentage of ubiquinone/total CoQ\(_{10}\), while plasma levels of CoQ\(_{10}\) were expressed as μg/ml.\(^{(16)}\)

**Mitochondrial membrane potential.** MMP was analyzed using the Nernstian dye 5',6,6'-tetracloro-1',1',3,3'-tetrabenzimidazolcarboxyamine iodide (JC-1) (Invitrogen, Monza, Italy). This cyanine dye is a lipophilic cation that is able to selectively enter in the mitochondria. The probe exists in a monomeric form emitting at 530 nm (green) upon excitation at 488 nm. However, with increasing MMP, JC-1 is able to form J-aggregates that are associated with a large shift in emission to 590 nm (red/orange) and mitochondrial membrane appears to be more polarized (above values about 80–100 mV the color of the dye changes reversibly from green to orange).\(^{(17)}\) After incubation with H\(_2\)O\(_2\), lymphocyte samples were washed twice in PBS and incubated in the dark for 15 min at 37°C with JC-1 (10 μg/ml) in complete medium. Subsequently cells were washed in PBS and analyzed using EPICS XL flow cytometer (Beckman Coulter, Milan, Italy). Emissions at 579 nm (FL1) and 590 nm (FL4) were detected. Photomultiplier tubes (PMTs) were set at 511 V and 938 V respectively. Compensation was set at FL1-FL4 10% and FL4-FL1 35%. A minimum of 10,000 events were recorded. Mitochondrial depolarization was evaluated in terms of percentage of cells showing low red fluorescence, proportional to MMP, using Win MDI. For bulk determination of the percentage of oxidative induced depolarization, 1 × 10\(^5\) lymphocytes/well were transferred to a 96 wells microplate, centrifuged at 400 g for 5 min in a Heraeus Multifuge 3S+ (Thermo Scientific, Milan, Italy) equipped with microplate rotor, to obtain a homogeneous distribution of cells on the bottom of plate. JC-1 fluorescence was assessed by using a microplate reader (Synergy HT, Winooski, VT) exciting the cells at 485/20 nm and reading the fluorescence emitted in the green at 528/20 nm and in the red at 590/20 nm. Mitochondrial depolarization was indicated by an increase in the green/red fluorescence intensity ratio. As a positive control of depolarization, cells were incubated with the uncoupling agent CCCP (200 μM) that produced 100% of depolarization.

**Intracellular ROS assay.** Intracellular ROS levels were assessed by means of DCFH-DA (2'-7'-dichlorodihydrofluorescein diacetate), a non-polar probe, which readily diffuses across cell membranes where it is hydrolyzed by intracellular esterases to the polar derivative, DCFH. In its reduced form DCFH is not expressed as percentage of cells showing low red fluorescence, proportional to MMP, using Win MDI. For bulk determination of the percentage of oxidative induced depolarization, 1 × 10\(^5\) lymphocytes/well were transferred to a 96 wells microplate, centrifuged at 400 g for 5 min in a Heraeus Multifuge 3S+ (Thermo Scientific, Milan, Italy) equipped with microplate rotor, to obtain a homogeneous distribution of cells on the bottom of plate. JC-1 fluorescence was assessed by using a microplate reader (Synergy HT, Winooski, VT) exciting the cells at 485/20 nm and reading the fluorescence emitted in the green at 528/20 nm and in the red at 590/20 nm. Mitochondrial depolarization was indicated by an increase in the green/red fluorescence intensity ratio. As a positive control of depolarization, cells were incubated with the uncoupling agent CCCP (200 μM) that produced 100% of depolarization.

**Comet assay.** Analysis was conducted on cryopreserved cells as described above. Immediately after thawing aliquots
containing 1,500 cells were washed in PBS. The supernatant was
removed and cells were resuspended in Low Melting Agarose
(LMA 0.7%) from which 50 μl were rapidly placed on high-
throughput comet slides (Trevigen) equipped with silicone barrier
delimiting 20 samples area per slide, pre-coated with 1% Normal
Melting Agarose (NMA 1%). Subsequently microgels were lysed
for at least 1 h at 4°C, in the dark in a freshly prepared lysis
solution (2.5 M NaCl, 100 mM Na₂EDTA, 10 mM Tris-HCl, 1% Triton X-100, and 10% DMSO, adjusted to pH 10). Finally DNA
was allowed to unwind in alkaline buffer (1 mM EDTA, 300 mM
NaOH, pH 13) for 30 min, in the dark and electrophoresed for
20 min at 1 V/cm in a refrigerated room. After electrophoresis,
slides were washed with 0.4 M Tris-HCl buffer (pH 7.5) for
5 min, dehydrated in 75% methanol and dried at 45°C for 20 min
about. Finally slides were stained by adding 15 μl of ethidium
bromide (20 μg/ml) and analyzed in fluorescence microscopy. For
each sample, 50 comets on two different slides (i.e., 100 comets/
sample) were assayed in each experiment. DNA damage was
evaluated by a custom-made computer-aided scoring and image
analysis software developed by our Department in collaboration
with the Engineering Department of the Polytechnic University of
Marche. This software has several advantages over commercial
software, allowing a semi-automatic analysis which greatly
reduces operator-dependent variability.(14) Results are reported
as percentage of DNA in the comet tail or tail intensity (TI)
for each cell expressed as means of the median at different
experimental points.

Statistical analysis. Mean, median and quartile values were
calculated and data are presented as box plots where the cross (x),
the box and the bars represents respectively the median, the 50%
and 25% of data distribution.***p<0.01 highly significant, **p<0.05 significant and *p<0.1 approaching significance.

Results

CoQ₁₀ bioavailability. Supplementation with 200 mg/day CoQ₁₀ for 2 weeks produced a significant increase in plasma levels
with median increase from 0.56 to 1.91 μg/ml (+241%, p<0.01) in
the overall studied population (Fig. 1A). Co-supplementation
with LA did not influence CoQ₁₀ bioavailability. Increased levels
of plasma CoQ₁₀ were associated with a change in its oxidative
status. As shown in Fig. 1B, supplementation with CoQ₁₀ pro-
duced a significant decrease of the percentage of ubiquinone/total
CoQ₁₀ with median decrease (from 15% to 8%, −47%, p<0.05)
indicating an increase of plasma antioxidant defenses. Also in
this case, co-supplementation with LA did not have a significant
influence on CoQ₁₀ oxidative status.

At cellular level, in basal conditions independently of supple-
mentation, there is a significant decrease in the percentage of
ubiquinone/total CoQ₁₀ with median decrease (from 92% to 72%,
−22%, p<0.05) (Fig. 1C). Moreover, this improvement of CoQ₁₀
oxidative status was associated with a decreased susceptibility
toward H₂O₂-mediated oxidation of CoQ₁₀. Exposure of PBL to
100 and 200 μM H₂O₂ for 4 h at 37°C produced a dose-dependent
oxidation of endogenous CoQ₁₀. Supplementation was effective
in protecting cellular ubiquinol from oxidation; in fact in the
samples treated with 100 μM of H₂O₂ the percentage of ubiqui-
none decreased, in terms of median values by 16% (from 97% to
81%); however remarkable inter-individual variability at this
collection concentration made this difference only approaching significance. On the contrary, those incubated with the higher dose of H₂O₂,
the extent of protection was highly significant (from 100% to
92%, −8%, p<0.01).

Plasma CoQ₁₀ levels at study entry (pre) and following 2-week supplementation (post) (A); % of ubiquinone/total CoQ₁₀ in plasma (B) and in PBL (C). Distribution of data relative to untreated control (ctrl), cells exposed to 100 μM (100) or 200 μM (200) H₂O₂. Data relative to 16 subjects are reported as box plot diagram where the cross (x), the box and the bars represent respectively the median, the 50% and 25% of data distribution.***p<0.01 highly significant, **p<0.05 significant and *p<0.1 approaching significance compared to study entry.

S. Silvestri et al.
Mitochondrial membrane potential. Incubation of PBL with JC-1 allowed determination of the MMP-dependent decrease in fluorescence associated with \( \text{H}_2\text{O}_2 \) exposure (Fig. 2A and B). Supplementation with \( \text{CoQ}_{10} \) alone produced an improvement of mitochondrial functionality, in terms of membrane potential, as shown by a decrease of the ratio between green (JC-1 monomers) and red fluorescence (J-aggregates) in basal condition (median values changed from 0.24 to 0.19, –22% that approached significance \( p < 0.1 \), Fig. 2A). These observations, conducted on the bulk population of cells using a fluorescence microplate reader, were further investigated at cellular level, by means of flow cytometric technique, in order to evaluate cellular population distributions in relation to MMP (Fig. 2B). Data are substantially in agreement with the bulk analysis, showing a decrease in the population of cells with low MMP following supplementation with antioxidants. In particular, this effect was more pronounced following oxidative insult (200 μM), where supplementation was able to significantly decrease the percentage of cells with low mitochondrial membrane potential in terms of median (from 63.4% to 55.5%, –12%, \( p < 0.05 \)). Factorial Anova did not show any significant difference in time between \( \text{CoQ}_{10} \) alone treatment and co-supplementation \( \text{CoQ}_{10} + \text{LA} \).

Intracellular ROS levels. Flow-cytometric analysis of intracellular DCFH-DA oxidation by endogenous ROS, allowed evaluation of the distribution of cells according to the intracellular oxidant status. As shown in Fig. 3A and B, exposure to \( \text{H}_2\text{O}_2 \) produced a dose-dependent decrease in cells characterized by low DCFH-DA fluorescence, associated with low content of intracellular ROS. Moreover, supplementation with tested mitochondrial nutrients significantly enhanced the oxidant-mediated increase in intracellular ROS. In particular, the extent of this decrease was highly significant following oxidative insult (200 μM) with median values changing from 13.9% to 5.8%, –58%, \( p < 0.01 \)). Similarly, also cells characterized by high content of intracellular ROS increased significantly following oxidative insult (200 μM) with a median change from 28.5% to 44.3%, +56%, \( p < 0.05 \)). Also in this case Factorial Anova did not show any significant difference in time between \( \text{CoQ}_{10} \) alone treatment and co-supplementation \( \text{CoQ}_{10} + \text{LA} \).

Oxidative DNA damage. Analysis by means of the alkaline version of the comet assay highlighted, as expected, low detectable levels of strand breaks in the DNA of healthy volunteers at study entry, with only 10% of the measured PBL producing comets with an average median of 5% of damaged DNA quantified as TI (Fig. 4). Incubation with 200 μM \( \text{H}_2\text{O}_2 \) for 4 h in complete medium produced very extensive DNA damage that did not allow quantification. Incubation with 100 μM \( \text{H}_2\text{O}_2 \) produced a highly significant increase of DNA damage showing a median TI of 34.6%. Supplementation with mitochondrial nutrients did not modify in a significant manner susceptibility of leukocyte DNA to

Fig. 2. Fluorescence signal proportional to mitochondrial membrane potential. Bulk measurement of monomeric dye JC-1 fluorescence in a microplate reader (A). Ratio green/red of JC-1 emission at study entry (pre) and following 2-week supplementation (post). Flow cytometric determination of JC-1 fluorescence at cellular level (B). Percentage of cells showing low MMP at study entry (pre) and following 2-week supplementaton (post). Distribution of data relative to untreated control (ctrl), cells exposed to 100 μM (100) or 200 μM (200) \( \text{H}_2\text{O}_2 \) are reported. Data relativities to 16 subjects are reported as box plot diagram where the cross (x), the box and the bars represent respectively the median, the 50% and 25% of data distribution.*** \( p < 0.01 \) highly significant, ** \( p < 0.05 \) significant and * \( p < 0.1 \) approaching significance compared to study entry.
oxidative stimuli, although a decrease of median TI value was observable. Factorial ANOVA did not show any significant difference in time between CoQ_{10} alone treatment and co-supplementation CoQ_{10} + LA.

Discussion

The present study focuses on oxidative stress and mitochondrial dysfunction in an *in vitro* model. In particular, we evaluated the effect of antioxidants with a clear mitochondrial target of preventing H_{2}O_{2} mediated oxidative damage and mitochondrial depolarization. The tested antioxidants were clearly able to significantly improve antioxidant status of plasma in supplemented subjects. In fact, CoQ_{10} is known to be transported by plasma lipoproteins and our data show that ubiquinone levels were inversely related to total CoQ_{10} content; this result is widely confirmed in the literature.\(^{(19)}\)

At cellular level, in PBL their antioxidant activity was more complex, in particular when cells were challenged with an oxidative stimulus. In fact, while the percentage of ubiquinone/total CoQ_{10} in cells was decreased in supplemented patients, as well as its susceptibility to oxidation following H_{2}O_{2} exposure, intracellular levels of ROS were slightly increased in basal conditions and remarkably following oxidative insult. This conflicting result suggests also a pro-oxidant activity at cellular level of CoQ_{10} and α-lipoic acid.

A large body of evidence points out that most, if not all, of the classical routes to transcriptional activation are modulated by redox processes or even critically depend on oxidant signals.\(^{(20)}\) Different redox-sensitive mammalian pathways of gene activation have been deeply investigated in the recent literature, in particular
the Nrf2 and NF-κB systems. CoQ₁₀ and lipoic acid have been shown to modulate the expression of these transcription factors and downstream pathways and observed pro-oxidant activities might justify a redox trigger to improved stress response.

These data are in agreement with Linnane et al. report that highlighted a pro-oxidant effect of CoQ₁₀ and LA; in this work he ascribed the beneficial effects of these molecules to a pro-oxidant effect that underlies adaptive responses in what could be defined as a para-hormetic mechanism involving radical signalling. In fact, despite an increase in intracellular ROS, in subjects supplemented with CoQ₁₀ and LA, we were able to show both an improvement of basal mitochondrial functionality and a protective effect toward oxidant-induced mitochondrial depolarization. Moreover, basal ROS increase following supplementation did not reach an extent able to promote oxidative DNA damage, highlighting its compatibility with physiological processes. Factorial Anova analysis was not able to highlight in our experimental model any additive effect of lipoic acid in association with CoQ₁₀; however large inter-individual variability might have contributed to an under-powered experimental design and data should be confirmed with a larger sample size.

Summarizing, we show that CoQ₁₀ and α-lipoic acid might have a double-edged behaviour in terms of its oxidative state that may vary according to the biological compartment considered. While antioxidant effect of ubiquinol in lipoproteins is widely verified and accepted, at cellular level, these so called mitochondrial nutrients, might shift their oxidative status modulating cellular redox-poise. In light of recent para-hormetic hypothesis this might contribute to promote the intracellular nucleophilic tone. In this sense, mitochondrial nutrients with antioxidant activity such as CoQ₁₀ and LA, differ from other antioxidant molecules such as vitamin C. In recent reports, it has been shown that high doses of these hydrophilic antioxidants are able to hamper ROS signalling induced by physical exercise abolishing adaptive response. These authors extended their conclusions to all types of antioxidants including CoQ₁₀ and LA, disregarding their chemical nature not mechanism of action. In this sense, the present study propose some contrasting evidences in line with a report by Sun et al. showing that in rats trained with endurance exercise, supplementation of the diet with mitochondrial nutrients, including antioxidants such as CoQ₁₀ and LA, were able to enhance exercise-induced mitochondrial biogenesis. Pro-oxidant activities of tested mitochondrial nutrients and consequent oxidant mediated signalling, might explain beneficial aspects associated with modulation of gene expression in the elderly. In these patients Linnane et al. showed that CoQ₁₀ was able to drive muscle gene expression toward type II fiber, fast contracting fibers that decrease more rapidly during ageing.

In conclusion, our data point out that, differently from other antioxidants, CoQ₁₀ and α-lipoic acid produce beneficial effects also steering intracellular redox poise toward a pro-oxidant environment. This interesting data deserves further investigations in an in vivo model of oxidative stress.

Acknowledgments

The authors are thankful to Pharmanord for supporting this research and providing the supplements. We also wish to thank the volunteers that participated in the study and Mrs. Monica Glebocki for her assistance in editing the manuscript and Dr. Annaluisa Tangorra for skillful technical assistance.
