Abstract
Eco-feedback is a design strategy that reminds users of their resource consumption as they use a product. The ultimate goal is to promote pro-environmental behaviors in users by making them aware of the environmental impact of their consumption. The way these designs present resource usage information can significantly impact user perceptions. This paper investigates two aspects of resource usage presentation, quantitative feedback and emotional evocativeness, by evaluating 32 designs spanning electricity, materials, transportation, and water via surveys of 619 university students in the US and Saudi Arabia. Both these aspects are positively correlated with perceived product appeal and perceived effectiveness in encouraging sustainable behavior. It was found that presenting quantitative resource usage information was more helpful to respondents who could better estimate resource consumption, while the emotional evocativeness of a design aided respondents with lower and higher resource consumption knowledge to a similar degree. In addition, we found that images of living creatures and strong visual cues evoked strong emotions in users. Female participants, in general, responded more strongly than males to this emotional evocativeness. These experimental findings cast light on how to better design eco-feedback products to be more widely accepted.

Keywords Product design · User-centered design · Eco-design · Sustainable product use · Emotional design

1 Introduction
Eco-feedback is a design strategy that presents users with information about resource consumption or environmental impact caused by product use (Tang and Bhamra 2008; Froehlich et al. 2010; McCalley and Midden 1998; Petersen et al. 2009). It is one of the product-led intervention strategies that aim to use products as a mechanism to promote pro-environmental behaviors in users (Deutz et al. 2010; Lilley et al. 2005; Sohn and Nam 2015). Traditional eco-design techniques such as environmental life cycle assessment (Finnveden et al. 2009) and planning (Kobayashi 2005) focus on reducing resource usage and controlling waste production during the manufacturing process (Mesa et al. 2018) and at a product’s end of life (Kroll and Hanft 1998; Rose et al. 2002). Common intervention efforts such as public campaigns (Fielding et al. 2013; Kurz et al. 2005; McKenzie-Mohr 2000) or educational programs (Boudet et al. 2016; Staats et al. 2004) aim to influence people’s environmental attitudes, increase their environmental knowledge, and further encourage sustainable behavior. Product-led intervention for sustainable behavior bridges these two approaches (Lilley 2009) and focuses on reducing a product’s environmental impact during the use phase (Bhamra et al. 2008; Rodriguez and Boks 2005; Telenko et al. 2008; Wever et al. 2008) and facilitate consumers to make green purchasing decisions (D’Souza et al. 2007).

An example of eco-feedback is an energy monitoring system that provides feedback on household electricity usage (Ueno et al. 2006). Another example is a beverage package labeled with an anti-littering message (Wever
Both of these have been proven effective in promoting pro-environmental behaviors such as conserving energy and reducing littering. Feedback or information on resource usage is generally believed to inspire short-term sustainable behaviors, and also increase users’ longer-term awareness and understanding about how everyday behaviors affect the environment (Froehlich et al. 2010). Compared to other product-led intervention design strategies such as “behavior steering” which encourages behavior change via embedded product constraints or affordances, and “smart” designs which automatically take actions to enforce behavior change, eco-feedback has the advantages of being less intrusive (Cor and Zwolinski 2015) and relatively easy and low-cost to implement (Shu et al. 2017). However, they are effective only when users are engaged (Telenko and Seepersad 2010) and can properly interpret the information (Järvi and Paloviita 2007), and their user acceptance is still limited (Barreto et al. 2013). These show the urgent need to gain a better, more rigorous understanding of how to make such products appealing to users and gain wider adoption.

This study takes the perspective that successful eco-designed products need to provide environmental benefits but also need to appeal to users and customers (Karlsson and Luttropp 2006). From a user-centered design point of view, seemingly small, but critical, details of a design can strongly impact whether a product is used effectively, whether a user’s experience is satisfying (Norman 2013), or whether a product is perceived as environmentally sustainable (Diego-Mas et al. 2016). For eco-feedback products, the way that resource usage information is presented is a key design concern (Fang and Hsu 2010; Froehlich et al. 2012). Subtleties in information presentation can make significant impacts on user perceptions, such as presenting a ranking of an individual’s consumption within a population versus presenting consumption relative to the population average (Aldrovandi et al. 2015). However, to date, there are few experimental studies of how different types of designs can influence users’ perception of eco-feedback information.

Traditionally, resource usage information is presented quantitatively (Froehlich et al. 2012) with the expectation that rational users, who make decisions to maximize their net benefit, will behave environmentally consciously once they are made aware of the environmental consequences of their behavior. For example, some cars are equipped with fuel economy meters that present the numerical miles-per-gallon of a vehicle under the assumption that drivers will change their driving patterns accordingly to save fuel and reduce greenhouse gas emission. However, this assumption often fails in practice and one study suggests that quantitative information tends to be effective only on those who already have strong pro-environmental intentions (Zachrisson and Boks 2012). In contrast, it is recognized that one’s environmental concerns and beliefs can be emotionally charged (Bang et al. 2000), and emotions such as anticipated regret or guilt are linked to consumers’ decision making including the selection of sustainable products (Goucher-Lambert et al. 2017) and services (Kim et al. 2013), and ecological behaviors such as recycling and use of public transportation (Carrus et al. 2008). In a prevailing notion from the area of Emotional Design, a successful product should not only have high functional performance but also deliver strong emotional value to the user (Boatwright and Cagan 2010; Norman 2004). Based on these, we hypothesize that an intervention design that is more emotionally engaging (Fang and Hsu 2010) will be more appealing to users.

This study compares two key aspects of the way resource usage information can be presented in eco-feedback designs, being quantitative and being emotionally evocative, and examines how they influence user perceptions and preferences. The research questions are:

Q1: How are quantitative and emotionally evocative usage information presented in an eco-feedback design linked to users’ evaluation of the design’s appeal and users’ perception of the design’s effectiveness in encouraging sustainable behavior?

We believe both quantitative and emotionally evocative aspects of resource usage can influence user perception, and expect that designs that present more quantitative resource usage information or evoke stronger emotions will be more appealing to users and be perceived as more effective in encouraging pro-environmental behaviors.

Q2: Do users with different levels of environmental awareness or quantitative resource consumption knowledge, or with different demographic backgrounds respond differently to the quantitative and emotional aspects of resource usage information presented in an eco-feedback design?

Previous studies have offered evidence that users who have different levels of environmental awareness and knowledge (Cor and Zwolinski 2015), motivations for sustainable behaviors (Srivastava and Shu 2015), and social orientations (pro-social or pro-self) (McCalley and Midden 2002) tend to react differently to intervention designs. Thus we consider preference heterogeneity among users, that not all people like the same designs (Feick et al. 1992; Windrum et al. 2009), and aim to identify design strategies specifically for different user groups.

To answer these questions, we generated four design forms of eight eco-feedback products, resulting in a total of 32 designs ranging from quantitative to emotionally evocative. Surveys were constructed and deployed among
university students to collect feedback and evaluations of these designs. Links between the design forms and user perceptions were analyzed. In the end, the implications of our findings and limitations of the study are discussed.

2 Methods

A substantial literature exists on methods for evaluating user responses to product-led interventions including eco-feedback designs (Daae and Boks 2015). These methods include testing immediate user reaction via surveys (Montazeri et al. 2012; Sohn and Nam 2015), testing short-term effectiveness of promoting sustainable behavior with in-lab experiments (Cor and Zwolinski 2015; MacDonald and She 2013; Montazeri et al. 2012), and testing product usability and long-term behavior change effectiveness with field studies (Montazeri et al. 2013; Weyer et al. 2008). Design representations such as rendered drawings (Sohn and Nam 2015), CAD models (Goucher-Lambert and Cagan 2015), and prototypes (MacDonald and She 2013; Montazeri et al. 2013) have been used to elicit user feedback on provisional ideas of sustainable products. This study surveys potential users across a wide geographical area for their responses to a relatively large variety of designs by presenting them with sketches of the designs.

A preliminary study (Bao et al. 2016) suggested the necessity for a broader, more comprehensive study to achieve conclusive results. In this present study, four resource categories were explored, within each category two products were identified. Four design forms of each of the eight products were generated, resulting in a total of 32 designs. Surveys collecting design evaluations were distributed among students in five universities in two countries, with 619 valid responses. Potential links between survey respondents’ preferences for specific designs to their personal characteristics, including gender, environmental awareness, and knowledge of resource consumption were examined.

2.1 Eco-feedback designs

Though many environment-related fields are worthy of study, a subset was selected that was directly linked to both the consumption of natural resources and the everyday lives of the general public: Electricity, Materials, Transportation, and Water. In addition, these categories were general enough to allow for a diverse range of products. Two products in each category were chosen: one providing dynamic feedback on resource usage and the other presenting static information that encourages a user to carry out sustainable behaviors.

Electricity:
- An **Electricity Meter** that monitors home electricity usage
- A **Light Switch** that reminds people to turn off the lights when leaving a room

Materials:
- A **Paper Towel Dispenser** that tracks how many paper towels have been consumed
- **Waste Cans** that separate landfill, recyclables, and compostable waste

Transportation:
- A **Fuel Economy Meter** that tracks the miles-per-gallon (MPG) of a vehicle
- A **Public-Transport Poster** that encourages the use of public transportation

Water:
- A **Water Tap** that monitors the day’s cumulative water usage
- A **Washing Machine** with a selectable water-saving mode

These products take their inspiration from the eco-design literature and a range of industrial design examples (Arroyo et al. 2005; Cor and Zwolinski 2015; Kuznetsov and Paulos 2010; Montazeri 2013; Montazeri et al. 2013; Petersen et al. 2009; Sohn and Nam 2015), and were believed to be products that student respondents would likely be familiar with. Visual representations of four versions of each of the products were generated, taking the following forms, respectively:

- **Text or Chart** displays resource usage information with clear, quantitative data
- **Visual Emphasis** attracts users’ attention through strong visual elements
- **Metaphor Using Objects** includes inanimate objects related to the environment or to resource consumption
- **Metaphor Using Living Creatures** incorporates animals or plants as reminders of the environment and resource usage

These design forms were drawn from existing literature and aimed to cover a range from quantitative to emotionally evocative. **Text or Chart** is a design form widely used in products such as water or energy dashboards (Agarwal and Weng 2009; Froehlich et al. 2012). **Visual Emphasis** draws on a basic technique in graphic design and user interface...
design (Galitz 2007) to draw a user’s attention to information through graphical elements. Examples include the battery icon on a mobile device, which turns red when the battery runs low. Metaphor is another common form in user interface design (Fishkin 2004) that makes analogies between the design and other concepts, and it has been used widely in product-led interventions (Fang and Hsu 2010; Montazeri 2013; Montazeri et al. 2013). Two types of Metaphors were explored: metaphor using inanimate objects, e.g. using a light bulb as an indicator of energy consumption, and metaphor using living creatures, e.g. using an image of a polar bear on a melting iceberg as a reminder of global warming. It was anticipated that images of living creatures would evoke strong emotions such as empathy for animals suffering from climate change, or hope for our ability to avoid future environmental damage (Swim and Bloodhart 2015).

Research suggests that when presenting representations to users, differences in fidelity and style can overshadow the content of a design (Macomber and Yang 2011). Thus these designs were hand-sketched by a single professional industrial designer to maintain a consistent visual style to mitigate potential evaluation bias (Häggman et al. 2015). Example designs are shown in Fig. 1. The top left product is an electricity meter that monitors home electricity usage. Designs 1–4 are varied forms of the meter showing cumulative daily usage. The second product is a washing machine with a selectable water-saving mode. Four versions of the water-saving mode button are shown. The Supplementary Material documents details of all 32 designs.

2.2 Survey development and implementation

A survey was constructed to ask respondents to evaluate and provide feedback on the eco-feedback designs. In addition, the survey evaluated respondents’ ability to estimate resources used in common daily activities and their awareness of environmental sustainability. Demographics including age, gender, year of school, major, university, and nationality were collected.

To avoid survey fatigue by presenting respondents with all 32 designs in a single survey, four distinct versions of the survey were created, each focusing on one resource category. Each respondent was randomly assigned to one version of the survey and was presented with resource estimation questions and in total eight designs of two products from one resource category. The awareness questions were the same across all surveys.

An online survey platform, Qualtrics, was used to create and deploy the survey. Pilot testing was conducted with four product design graduate students for timing, wording, and reading level. Their feedback was used to refine the survey.

2.2.1 Survey part I: resource consumption knowledge and environmental awareness

Respondents’ knowledge of resource consumption for Electricity, Water, Materials, or Transportation was evaluated. In the Electricity and Water versions, respondents were asked to estimate the electricity or water usage in common daily activities, such as using a laptop computer for an hour (Attari et al. 2010), or running a washing machine for one cycle. In the Materials version, respondents were asked to differentiate recyclable and compostable waste from landfills. For Transportation, respondents were asked to estimate the CO₂ emissions of different modes of transportation.

The usage and emission estimation questions were presented as logarithmic sliders to emphasize orders of magnitude rather than precise values. Respondents were not...
expected to know exact values for these activities and thus were asked to give rough estimates. To aid estimation, reference points were provided, such as the electricity consumed by a single light bulb. Respondents could choose to view the survey in either SI or Imperial units. Multiple online resources including the website of the United States Environmental Protection Agency were referred to in developing answers for these questions (see Supplementary Material for more information). For devices whose resource consumption may vary by model, brand, or working condition, standard devices with typical consumption rates were selected as the reference.

Eight questions were used to evaluate the respondents’ environmental awareness: six asking the survey respondents to rate if they agreed or disagreed with statements regarding natural resources and the environment, and two asking the respondent to self-report their environmental awareness and environmental friendliness of their lifestyle on 1–5 Likert scales. These questions were adapted from the New Ecological Paradigm scale (Dunlap et al. 2000), a widely used measure of environmental concern; and the section of Attari, et al.’s Survey on Energy (Attari et al. 2016) that measures environmental attitude.

### 2.2.2 Survey part II: design evaluation questionnaire

The survey first presented the designs in random sequence and asked respondents to rate them using 1–5 Likert scales on four criteria:

- **Clarity**: How clearly did the design show resource usage/Clarity is a measurement of how individuals perceive quantitative resource usage information, while Emotion measures the overall intensity of emotions evoked by the designs. Effectiveness looks at the designs’ potential influence on user-product interaction behavior as perceived by respondents. Appeal is an overall evaluation of how attractive or desirable users find a design to be. Optional open-ended comment areas were provided for respondents to elaborate on their ratings.

  While the first two criteria directly evaluate the two aspects that are of interest in this study (quantitative vs. emotional), the latter two serve as evaluations for the perceived quality of the overall designs. These criteria are independent measurements as a user would not necessarily find a design effective or appealing even though they find it presents clear information and/or evokes strong emotion. However, we still expected the ratings to be correlated. We should note that all four criteria were subjective measurements from individual respondents, and thus variations of ratings were expected. Therefore, average ratings for each design were calculated for further analysis.

  After rating each of four designs of one product, respondents were presented with all four designs at the same time in a randomized sequence and were asked to select one that they would choose for themselves, known as a “most preferred” choice (Luce 2005; McFadden 2001). These choice questions simulated consumers selecting one product out of a group of similar products, with attempts to approximate their potential purchasing/adoption decisions. In the example of the electricity meter, respondents were presented with the four electricity meter designs at the same time and were asked, “Imagine you were selecting an electricity meter for your apartment. Which one of the designs would you prefer the most?” If the product was not something individuals would purchase for themselves, they were asked to think about the product they would select for their community (e.g., their university). Based on consumer preference theory, one would choose the design that was the most desirable, all things considered (Frank and Glass 1991). Again, optional comment areas were provided for respondents to elaborate on their responses.

  The Supplementary Material documents more details and presents examples of the survey questions.

### 2.2.3 Survey distribution and quality control

The survey link was sent with a recruiting email to campus housing email lists, departmental email lists, course email lists, and relevant student clubs’ email lists. Students voluntarily took the survey. US participants were provided with the chance to be entered in a lottery for Amazon gift cards of $10, $20, and $50. The entrance into the lottery was independent of the survey responses, and thus we believe no bias was induced with the incentive. No incentives were provided to the Saudi Arabian participants.

The following screening rules were applied to ensure data quality:

- Respondents had to spend at least 5 min completing the survey. This minimum time was selected because it was the fastest time the researchers themselves could complete the survey while reading all questions and
providing meaningful responses (Kittur et al. 2008; Mason and Suri 2012).

- Respondents with resource consumption knowledge scores less than 1.5 interquartile ranges below the first quartile were considered outliers and were excluded from further analysis. This rule was enacted after observing illogical responses to knowledge questions, such as using the default starting points of the slider bars as answers to all questions.

### 2.3 Data analysis

#### 2.3.1 Resource consumption knowledge score and environmental awareness score

For the Material usage questions, respondents received one point each time they chose the correct way of disposing of a particular type of waste, with a maximum possible score of ten points. For the Electricity, Transportation and Water surveys, the score for each respondent’s knowledge level of resource usage was calculated using the proposed equation:

\[
\text{Knowledge Score}_i = 10 - \sum_{k=1}^{K} \left| \log \left( \frac{E_{ik}}{S_k} \right) \right|, \quad (1)
\]

\(E_{ik}\) is the respondent \(i\)'s answer for question \(k\), \(K\) is the total number of questions, varying from four to six for different versions of the survey. Each question is weighted equally. \(S_k\) is the standard (correct) answer for questions \(k\). The difference between the logarithms of these two values was calculated. Logarithms allow the measurement of the difference in magnitude between two values rather than arriving at an exact number. The log differences for all questions were summed together and subtracted from 10. This subtraction provided a positive knowledge score that represented the resource usage estimation accuracy. The larger the accumulated differences between estimates and standard answers, the lower the knowledge score; the closer the estimations to the standard answers, the higher the knowledge scores. The knowledge scores of different resource categories should not be compared to each other.

Each answer in the environmental awareness questionnaire was coded from 1 to 5, with responses indicating the most positive attitude towards the environment receiving a score of 5 and the most negative attitude a score of 1. Scores for the eight questions were added together to form a single “Awareness Score”, varying from a minimum of 8 to a maximum of 40. The higher the score, the more environmentally aware the respondent was assumed to be.

Median knowledge scores of each resource category were used to split respondents into a “higher knowledge” group and a “lower knowledge” group. Similarly, median awareness scores were used to split respondents into “higher awareness” and “lower awareness” groups. Preference models will be compared between these groups later to answer the second research question. We choose to use this median split method for its conceptual clarity.

#### 2.3.2 Design choice modeling

Conditional logistic regression models were constructed to determine whether there were any relationships between design ratings and respondents’ choices of most preferred designs (McFadden 1973; Train 2002). The probability that the \(i\)th design being chosen among the four designs of any product was:

\[
P_i = \frac{\exp(\beta \cdot X_i)}{\sum_{j=1}^{4} \exp(\beta \cdot X_j)}, \quad i = 1, 2, 3, 4, \quad (2)
\]

where \(X_i\) was a vector of averaged ratings of the evaluation criteria for design \(i\), and \(\beta\) was a vector of model coefficients. No intercept was included in the model for two reasons: first, design ratings were confounded with forms of design (Text or Chart designs on average had higher clarity ratings, and Metaphor Using Living Creatures designs, in general, had higher emotion ratings), thus estimating intercepts would cause the problem of collinearity; and second, each set of four designs was presented in random order, eliminating potential bias introduced by the presentation sequence.

Choice data from the four resource categories were pooled to construct the models. Ratings were normalized to range from 0 to 1 before fitting to the model so that the model coefficients could be used directly to compare the importance of the explanatory variables. R package mlogit (Croissant 2012) was utilized to estimate the model with the maximum likelihood method.

#### 2.3.3 Investigating the influence of demographic background

This study also noted how the demographic factors of the survey respondents might be related to their resource consumption knowledge, environmental awareness, and choices of designs. Because virtually all respondents were university students around a similar age, the analysis focused on the potential influence of the country (US or Saudi Arabia) and gender of the survey respondents.

To understand the impact of the quantitative and the emotional aspects of a design on the selection of most preferred designs in different respondent groups, logistic regression models were fitted to the following groups, respectively: female and male, higher and lower resource consumption knowledge groups, and higher and lower environmental awareness groups. To compare preferences between different groups of respondents, a two-tailed Z-test was used with a
large sample assumption to compare the coefficients of different models (Clogg et al. 1995; Paternoster et al. 1998):

$$Z = \frac{|\beta_1 - \beta_2|}{\sqrt{SE\beta_1^2 + SE\beta_2^2}}.$$  \hspace{1cm} (3)

where $\beta_1$ and $\beta_2$ were the corresponding coefficients from model 1 and model 2 respectively, and the $SE\beta_1$ and $SE\beta_2$ were their standard errors. A significance level of 0.05 was selected. The two-tailed p-values were calculated as:

$$p = 2 \times [1 - \Phi(Z)],$$  \hspace{1cm} (4)

where $\Phi(Z)$ is the cumulative normal distribution function of $Z$.

### 3 Results

#### 3.1 Study participants

The survey was distributed among undergraduate and graduate students at one US co-educational technology institute, one US women’s liberal arts college, one all-male Saudi Arabian technology university, and two all-female Saudi Arabian universities. In total, 1018 surveys were initiated of which 658 were completed, corresponding to a 65% completion rate. After applying two screening rules, 619 valid responses (94% of completed responses) remained. Four responses were left out from the analysis to maintain the anonymity of the results. They do not influence the results of the study, resulting in 615 responses. Table 1 summarizes the country and gender distribution of the valid responses.

The sample sizes in US and Saudi Arabia provided 5% and 6% margin of error, respectively, with 95% confidence level for enrolled university students in the two countries. The respondents formed a convenience sample that consisted of students from freshman to PhD and from various departments including science, engineering, social science, and arts, which covered a varied background. The proportion of female and male students were imbalanced, constrained by gender distributions of the surveyed university populations. However, sufficient data were collected in each group (the smallest group had 21 respondents), which allowed meaningful statistical comparison.

**Table 1** Summary of valid survey responses

| Country  | Electricity | Material | Transportation | Water | Total |
|----------|-------------|----------|----------------|-------|-------|
| A        | 81 (F:60, M:21) | 109 (F:77, M:32) | 78 (F:51, M:27) | 99 (F:73, M:26) | 367 (F:261, M:106) |
| B        | 61 (F:25, M:36) | 60 (F:28 M:32) | 62 (F:29, M:33) | 65 (F:24, M:41) | 248 (F:106, M:142) |
| Total    | 142 (F:85, M:57) | 169 (F:105, M:64) | 140 (F:80, M:60) | 164 (F:97, M:67) | 615 (F:367, M:248) |

$F$ female, $M$ male

**Fig. 2** Distributions of knowledge scores and awareness scores by country and gender. Note: The dots and the error bars represent the average scores and the standard deviation of scores, respectively, from each group of respondents of the same gender and country.
3.2 Resource consumption knowledge scores and environmental awareness scores

The means and the standard deviations of the knowledge scores for each resource category as well as the environmental awareness scores were calculated for each group of respondents of the same gender and country (see Fig. 2). Higher knowledge scores represent a higher ability to estimate resource consumption. Not surprisingly, students from technical majors had higher knowledge scores overall compared to non-technical students (Bao et al. 2016). Higher awareness scores indicate higher environmental awareness.

Two-way ANOVA (analysis of variance) was conducted to compare knowledge and awareness scores between countries and genders. The results are summarized in Table 2. No significant differences were detected between female and male respondents for knowledge scores in Material, Transportation, and Water category. However, respondents from country A had consistently higher knowledge scores for these three categories across both genders. The Electricity category was an exception: country B male respondents had significantly higher knowledge scores compared to country B female respondents regarding electricity consumption. For the awareness scores, the interaction effect between country and gender was statistically significant at a 0.05 level. However, the effect of the country was much more significant, indicating that the main difference in awareness scores was between countries rather than between genders. Overall, the differences in resource usage knowledge and environmental awareness scores were much more significant between the two countries, while gender had small or no differences regarding these two scores.

3.3 Design ratings

The average clarity ratings and emotion ratings of each design are plotted in Fig. 3. As expected, more quantitative designs featuring Text or Chart had high clarity ratings but relatively low emotion ratings, presumably because they presented concise but dry information on resource usage. Some respondents liked such information as they commented: “it is interesting to see how consumption accumulates in a day”, while the others were overwhelmed by the details as they pointed out that the Text or Chart designs have “too many words”. In contrast, designs featuring Metaphor Using Living Creatures had high Emotion ratings but relatively low Clarity ratings, possibly because the images of animals and plants were evocative but lacked precision in presenting resource usage information. As respondents wrote: “animal figures have more emotional effect for raising awareness”, “this design (with the whale image) makes you feel like you are saving a life”. Designs with Visual Emphasis fell between these two, with relatively high ratings for both clarity and emotion as they are “simple and visual” and “quickly draw attention”. Designs created by Metaphor Using Objects lie on the bottom left side of the figure, with lower ratings on average for both aspects. We found that the links between objects and the environment were less obvious than that between animals/plants and the environment. For example, respondents would not always associate a light bulb with energy conservation (E1) or a water bottle with water conservation (W1).

Table 2 Two-way ANOVA of knowledge scores and awareness scores between countries and genders

|                    | Knowledge scores | Awareness scores |
|--------------------|------------------|------------------|
|                    | Electricity      | Material         | Transportation | Water          |
| Country            | 5.944 (0.016*)   | 31.320 (<0.001***) | 16.799 (<0.001***) | 22.124 (<0.001***) | 126.041 (<0.001****) |
| Gender             | 7.826 (0.006**)  | 0.132 (0.717)    | 0.406 (0.525)   | 1.141 (0.287)   | 1.420 (0.234)       |
| interaction        | 14.029 (<0.001***)| 0.652 (0.421)    | 0.722 (0.397)   | 0.357 (0.551)   | 4.598 (0.032*)      |

Two-way ANOVA results significantly on level of 0.05 are highlighted with italic, *p<0.05, **p<0.01, ***p<0.001
all four ratings of each design are summarized in the Supplementary Material.

Large variances of the average ratings existed among products of the same form. Taking the electricity meter (E1) designs and the washing machine (W2) designs (shown in Fig. 1) as examples, these two products in form of Visual Emphasis had noticeable differences in both clarity and emotion ratings (as can be seen in Fig. 3), presumably because the electricity meter design had many more visual elements, including a number representing accumulated electricity usage, a colored scale and an indicator of current usage, while the washing machine design only had colored buttons. In the scope of the current study, it would be hard to distinguish users’ responses to the different visual elements on a single design.

Pearson correlation coefficients between the average ratings are summarized in Table 3. Effectiveness ratings were statistically significantly correlated with both Clarity and Emotion ratings; Appeal ratings were also correlated with Clarity and Emotion ratings. In addition, Effectiveness and Appeal ratings were highly correlated with each other. These results indicate that designs that presented clearer information and evoked stronger emotions were more likely to be perceived as effective in encouraging resource conservation behavior and were more likely to be perceived as appealing.

### 3.4 Most preferred design choices

Overall, designs featuring Visual Emphasis were voted by the highest percentage of participants as “most preferred,” followed by designs featuring Text or Chart and Metaphors Using Living Creatures. Figure 4 presents three designs that were voted as the “most preferred” by the majority or plurality of respondents. From left to right they are: an electricity meter design (E1) featuring Visual Emphasis, a paper towel dispenser design (M1) featuring Metaphor Using Living Creature, and a waste cans design (M2) featuring Text or Chart. They either had a high clarity rating (the waste cans) or high emotion rating (the paper towel dispenser), or both (the electricity meter). Figure 3 can be referred to for the clarity and emotion ratings of these designs.

In the open-ended comments section of the survey, some respondents reported that they chose their most preferred design because it was “the most emotionally powerful”, “the most evocative, and has the strongest emotional response”; while the others preferred to see more data and detailed information: “It’s a lot clearer than the other”, “It is the most informative and straightforward”, “Considering resources (consumption) should be rational and practical, not emotional”.

Logistic regression model as described in Eq. (2) was used to capture the relationship between the respondents’ choices and the average ratings of evaluation criteria for each design. As similar trends were observed across the four

| Table 3 Pearson correlation coefficients (p values) between average design ratings |
|--------------------------------------|------------------|-----------------|-----------------|
|                                     | Clarity          | Emotion         | Effectiveness   | Appeal          |
| Clarity                             | 1                | 0.312 (0.082)   | 0.734 (<0.001***) | 0.769 (<0.001***) |
| Emotion                             | –                | 1               | 0.634 (<0.001***) | 0.716 (<0.001***) |
| Effectiveness                       | –                | –               | 1               | 0.922 (<0.001***) |
| Appeal                              | –                | –               | –               | 1               |

*p < 0.05, **p < 0.01, ***p < 0.001

Fig. 4 Example designs winning a majority or plurality votes as the most preferred. The left figure is reproduced with permission from ref (Bao et al. 2016), © 2016 ASME
resource categories, and creating choice models within each specific category would significantly reduce the sample sizes and thus the statistical power of the analysis, choice data from all participants (in total \( N = 1238 \) choices, two choices per respondent) was pooled to fit this model.

The average clarity and emotion ratings were included in the choice model as explanatory variables. The effectiveness and appeal ratings were highly correlated with the clarity as well as with the emotion ratings as described in Sect. 3.3, and thus were excluded from this model to avoid collinearity. The coefficient for Clarity was \( 1.71 \pm 0.13 \) (\( t \)-value = 13.60, \( p \)-value < 0.001) and the coefficient for Emotion was \( 1.29 \pm 0.14 \) (\( t \)-value = 9.12, \( p \)-value < 0.001), both positive and statistically significant at a 0.05 level (model log-likelihood = −1532.8). This confirmed that quantitative resource consumption information and emotional evocativeness both played important roles in influencing respondents’ choices of their most preferred designs.

When the average effectiveness and the average appeal ratings were included in choice models on their own, their model coefficients were \( 3.14 \pm 0.17 \) (\( t \)-value = 18.71, \( p \)-value < 0.001) and \( 2.68 \pm 0.14 \) (\( t \)-value = 18.72, \( p \)-value < 0.001), respectively, and their model log-likelihoods were −1491.6 and −1497, respectively. Again, these coefficients were positive and statistically significant at a 0.05 level, showing the “most preferred” design choices also tended to be those rated as effective in encouraging sustainable behavior and overall more appealing.

### 3.5 Comparing preferred design choices between demographic groups

This analysis focused on comparing respondents’ reaction towards the quantitative and emotional aspects of the designs, and thus only included average clarity and emotion ratings as explanatory variables when comparing preferences between demographic groups. To eliminate potential confounding effects between knowledge scores, awareness scores, and countries (country A respondents had, on average, higher knowledge scores and higher awareness scores compared to country B, as discussed in Sect. 3.2), logistic regression models were fitted to the higher and lower knowledge groups/awareness groups within each country. Higher and lower knowledge/awareness groups were constructed within each country using the median scores of that country. The preference models of females and males were also compared within each country to eliminate the potential bias induced by unbalanced sample sizes of different gender and country groups. Choice data for electricity-related products from Country B were excluded from the models to eliminate confounding between gender and knowledge scores. Comparisons of the model coefficients are summarized in Fig. 5. Model coefficients are documented in Supplementary Material.

In both country A and country B, females had significantly higher emotion coefficients compared to males, while there were no significant differences between their clarity coefficients. Again in both countries, the higher knowledge groups (top 50% knowledge scores) had significantly higher clarity coefficients, but not significantly different emotion coefficients, compared to the lower knowledge groups (bottom 50% knowledge scores). Both clarity and emotion coefficients were not statistically different between the high awareness groups (top 50% awareness scores) and the lower awareness groups (bottom 50% awareness scores). It would be interesting to investigate the impact of cultural differences between countries. However, in the data we collected, the country was confounded with knowledge score and gender (country A respondents had higher overall knowledge scores and a higher female to male ratio), which would likely bias the result. Therefore, a direct comparison between countries was not conducted.

The differences between choice models of females and males suggested that the emotional aspect of a design had much more influence on female respondents’ choices of most preferred designs than on male respondents. The quantitative aspect of a design appeared to be much more important to respondents who had higher resource consumption knowledge scores, indicating that respondents who were better at estimating resource consumption or possess more knowledge about resource consumption were more engaged with the quantitative resource usage data provided by the eco-feedback designs.

### 4 Discussion

Key findings regarding the original research questions are highlighted and discussed below, as well as the study limitations and directions for future work:

Q1: How are quantitative and emotionally evocative usage information presented in an eco-feedback design linked to users’ evaluation of the design’s appeal and users’ perception of the design’s effectiveness in encouraging sustainable behavior?

Traditional theoretical frameworks such as theory of reasoned action, theory of planned behavior, and value-belief-norm theory (Kollmuss and Agyeman 2002; Oreg and Katz-gerro 2006) were developed to predict pro-environmental behavior with people’s environmental knowledge and attitude. In addition, numerous empirical studies have explored the links between attitude, knowledge and behavior (Bradley et al. 1999; Meinhold and Malkus 2005). Only recently have the impact of emotions on motivating sustainable behavior and moderating environmental belief and attitude gained attention (Bang et al. 2000;
Our study took a product-design perspective and investigated the presentation of resource usage information on products, with the emphasis not only on quantitative feedback but also on the emotional evocativeness of the information presented. The results demonstrated that both quantitative resource usage information and emotional power of a design were important to the success of designs we evaluated in the sense that designs with higher clarity ratings and higher emotion ratings tended to be rated as more appealing, more effective in encouraging sustainable behavior, and were more...

Fig. 5 Comparison of logistic regression model coefficients between genders, higher and lower knowledge groups, higher and lower awareness groups within each country. Note: Blue bars and pink bars represent the estimated model coefficients of clarity ratings and emotion ratings, respectively. Error bars represent the standard errors of coefficients. frequently chosen as the most preferred. This study did not examine the emotional valence or the specific type of emotions that were evoked by the designs. Different emotions may have different influences on user perception and preference (Lerner and Keltner 2000). While positive emotions (such as satisfaction) could encourage users to be more involved with environmentally sustainable practices, negative emotions such as guilt might drive users away from further engagement with the products (MacDonald and She 2015). A richer understanding of the types of emotions evoked by a design and their effectiveness in encouraging pro-environmental behaviors is an area ripe for further study (Bao et al. 2018).

In addition, the Effectiveness and Appeal ratings for designs were highly correlated. It may be that users were more attracted to designs they believed could spark environmentally-conscious behaviors; on the other hand, it is well known that designs that are more visually attractive are generally perceived to be more effective and work better (Kurosu and Kashimura 1995; Tractinsky et al. 2000), regardless of whether they actually are. One limitation of this study is that the results were immediate user evaluations of designs. Gap between the perceived effectiveness of a design and actual effectiveness of a product in promoting pro-environmental user behaviors likely exists. Also, stated design preference cannot be directly translated to market success since factors such as cost are not considered. Investigating consumers’ willingness-to-buy with product prices considered; monitoring longer-term user-product interactions, and investigating the designs’ actual impact in encouraging sustainable behavior change, establishing habits, and changing values and beliefs concerning the environment would be exciting directions for future work.

Q2: Do users with different levels of environmental awareness or quantitative resource consumption knowledge, or with different demographic backgrounds respond differently to the quantitative and emotional aspects of resource usage information presented in an eco-feedback design?

The quantitative and the emotional aspects of resource usage information can influence users’ thinking process but in different ways. Quantitative usage might prompt users to think about their consumption in a logical and active manner known as system 2 thinking (Kahneman 2011), and thus whether a user responds to it could largely depend on their ability to properly interpret the information (environmental knowledge) and their willingness to take the effort to interpret the information (environmental awareness). Not surprising, significant evidence was found that respondents with higher resource consumption knowledge scores were much more sensitive to the quantitative aspect of a design compared to respondents whose knowledge scores were lower. This illustrates a limitation of presenting merely quantitative resource usage information—to users who know little about resource consumption, the quantitative data might not be very attractive or informative, let alone encourage sustainable behaviors, just as calorie labeling of food does little for those who lack the understanding of calorie information (Bollinger et al. 2011; Elbel et al. 2009).

The emotional aspect, on the contrary, might prompt users to react in a faster and automatic manner (system 1 thinking). It was found that respondents were sensitive to the emotional aspect of designs to a similar degree, regardless of their resource consumption knowledge scores. This finding is useful as it provides guidelines to enlarge the impact of eco-designs by emotionally engaging a broader audience of users, including those who do not possess much quantitative knowledge about resource consumption. In addition, female respondents were found to be more sensitive to the emotional aspects of the design than male respondents, consistent with empirical evidence that women generally respond more emotionally to visual stimuli than men (Grossman and Wood 1993). This finding can help form principles for designing compelling eco-feedback products for specific genders.

Contrary to our expectation, no significant difference in design preferences was found between respondents with higher or lower environmental awareness scores. The environmental awareness evaluation questions in this study were built upon existing measures of pro-environmental attitude (Attari et al. 2016; Dunlap et al. 2000). However, self-reported environmental awareness can be subjective, and validations of the measurements should be conducted in future work.

We believe the four categories (electricity, material, transportation, and water) explored in the study covered a large enough range of resources and environment-related fields to provide generalizable results. However, the eco-feedback strategy presented could be applied to other categories, such as encouraging a low-carbon diet (De Boer et al. 2016) or reducing food waste (Venkat 2011). In this study, design evaluation was collected from university students. Though the students we surveyed covered a large variety of demographic backgrounds, in future studies, it would be beneficial to conduct the study with participants that are not limited to the student population.

Four forms of designs were investigated in this study. Visual Emphasis was shown to be an effective design form. On average, this type of design had the highest ratings on both clarity and emotion and tended to receive more votes than the most preferred designs. Meanwhile, Text or Chart and Metaphor Using Living Creatures were demonstrated to be the most quantitative and the most emotionally evocative design forms, respectively. However, it should be noted that the forms of the design were intentionally isolated in this study so that their influence could be examined separately. In
addition, the survey participants were evaluating each design holistically. In practice, designers should not be obligated to follow a single form of design. Instead, they should adjust, combine, or create new design forms as needed. Other forms of design and ways of presenting resource usage information that are worthy of study include setting goals for resource conservation (Abrahamse et al. 2007) or gamifying the resource conservation process (Gustafsson et al. 2009).

5 Conclusions

This study investigated an eco-design strategy known as eco-feedback design. This strategy explicitly presents product resource consumption information as a way of encouraging sustainable product use. The stance of the work was consistent with other research that investigates the social and psychological aspects of eco-design implementation (Boks 2006; MacDonald and She 2015) and bridged the gap between the technical aspects of eco-design development (Rounds and Cooper 2002) and interventions for promoting resource conservation behavior (Nahiduzzaman et al. 2018).

This work focuses on evaluating different design forms and their impact on user perceptions of designs. It contributed to the rich literature of eco-design by presenting an experimental and evidence-based approach that elicits user feedback for conceptual designs in the early stage of product design and development. We evaluated how users perceive thirty-two intervention designs of household products in four resource categories, including electricity, water, materials, and transportation. Four design forms were explored, covering a range from quantitative to emotionally evocative. We mapped the designs to a 2D space of quantitative and emotional, and demonstrated that both the quantitative and emotional power of a design were important to the success of these products in the sense that designs rated to show clearer resource usage information and evoke stronger emotions tended to be rated as more appealing, perceived as more effective in encouraging sustainable behavior, and more frequently chosen as the most preferred designs. In addition, we found significant preference differences concerning the quantitative and emotional aspects of resource usage information between respondents with different resource consumption knowledge scores and between male and female respondents, respectively.

These findings challenge the traditional strategies of designing eco-feedback products whose single focus was on presenting quantitative information and point to the direction of creating designs that can better engage users emotionally. The four specific design forms investigated in the study have implications for ways of designing and developing these products in practice. In addition, the methods established in this study that collect user feedback on provisional design representations could be used by designers to accelerate the development of all kinds of sustainable products.
