Abstract

We study internal stability in the context of diffusively-coupled control architectures, common in multi-agent systems (i.e. the celebrated consensus protocol), for linear time-invariant agents. We derive a condition under which the system cannot be stabilized by any controller from that class. In the finite-dimensional case the condition states that diffusive controllers cannot stabilize agents that share common unstable dynamics, directions included. This class always contains the group of homogeneous unstable agents, by any controller from that class. In the finite-dimensional case the condition states that diffusive controllers cannot stabilize agents with a static interaction network.

This work studies a class of distributed control laws, where only relative measurements are exchanged between neighbors. In other words, each agent has access only to the difference between its output and that of each of its neighbors. Such control laws are called \textit{diffusive} and systems controlled by them are known as \textit{diffusively coupled}. Diffusive control laws are common in the MAS literature. Relative sensing appears naturally in MAS tasks, where absolute measurements are hard to obtain, such as space and aerial exploration and sensor localization, see (Smith and Hadaegh, 2005; Khan et al., 2009; Zelazo and Mesbahi, 2011b) and the references therein. The consensus and synchronization problems are well-known examples of diffusively coupled systems (Olfati-Saber et al., 2007; Wieland et al., 2011).

However, diffusively-coupled systems behave poorly when affected by disturbances and noise. Measurement noise rapidly deteriorates performance (Zelazo and Mesbahi, 2011a, §III-A) and even dynamic controllers can hardly attenuate disturbances (Ding, 2015). To cope with the difficulties, different relaxing assumptions are assumed. Some allow for non-relative state (Yucelen and Egerstedt, 2012) or output (Mo and Guo, 2019) measurements, while others employ an undisturbed leader (Ding, 2015) or impose limitations even on bounded disturbances (Bürger and De Persis, 2015 Prop. 5). Despite these different assumptions, if they fail, the resulting trajectories exhibit certain common traits that can be associated with instability. These traits can be illustrated by the classical consensus protocol, considered below for a set of integrator agents with a static interaction network.

1. Introduction

A multi-agent system (MAS) is a collection of independent systems (agents) coupled via the pursuit of a common goal. In large-scale MASs the information exchange between agents might be costly. As such, it is commonly limited to a subset of agents, known as \textit{neighbors}. Control laws that use only information from neighboring agents are called \textit{distributed}.

This work studies a class of distributed control laws, where only relative measurements are exchanged between neighbors. In other words, each agent has access only to the difference between its output and that of each of its neighbors. Such control laws are called \textit{diffusive} and systems controlled by them are known as \textit{diffusively coupled}. Diffusive control laws are common in the MAS literature. Relative sensing appears naturally in MAS tasks, where absolute measurements are hard to obtain, such as space and aerial exploration and sensor localization, see (Smith and Hadaegh, 2005; Khan et al., 2009; Zelazo and Mesbahi, 2011b) and the references therein. The consensus and synchronization problems are well-known examples of diffusively coupled systems (Olfati-Saber et al., 2007; Wieland et al., 2011).

However, diffusively-coupled systems behave poorly when affected by disturbances and noise. Measurement noise rapidly deteriorates performance (Zelazo and Mesbahi, 2011a, §III-A) and even dynamic controllers can hardly attenuate disturbances (Ding, 2015). To cope with the difficulties, different relaxing assumptions are assumed. Some allow for non-relative state (Yucelen and Egerstedt, 2012) or output (Mo and Guo, 2019) measurements, while others employ an undisturbed leader (Ding, 2015) or impose limitations even on bounded disturbances (Bürger and De Persis, 2015 Prop. 5). Despite these different assumptions, if they fail, the resulting trajectories exhibit certain common traits that can be associated with instability. These traits can be illustrated by the classical consensus protocol, considered below for a set of integrator agents with a static interaction network.

1.1. Motivating example

Reaching agreement between autonomous agents is a fundamental building block in multi-agent coordination (Ren and Beard, 2008). In its simplest form it studies a group of independent integrator agents \( x_i(t) = u_i(t) \), where \( x_i \) and \( u_i \) are their states and control inputs, respectively. The goal is to reach asymptotic agreement between all agents, in the sense that

\[
\lim_{t \to \infty} (x_i(t) - x_j(t)) = 0, \quad \forall i, j, \quad (1)
\]

under the constraint that the \( i \)th agent has access only to states of its neighbors, whose indices belong to a set \( \mathcal{N}_i \). This problem can be solved by the celebrated consensus protocol (Olfati-Saber et al., 2007), which is a diffusive state-feedback of the form

\[
u_i(t) = -\sum_{j \in \mathcal{N}_i} (x_i(t) - x_j(t)), \quad \forall i. \quad (2)
\]

If certain connectivity conditions on the communication topology hold (i.e. connectedness), then the control law (2) drives the agents to agreement exponentially fast (Mesbahi and Egerstedt, 2010, Ch. 3). The state trajectories of four agents controlled...
The control signals response.

un boundedness of the control signals under such conditions is intriguing. It is caused by unstable pole-zero cancellations in the feedback loop (Zhou et al., 1996, Sec. 5.3). However, controller (2) is static and thus has no zeros.

Situations wherein some signals in the closed-loop system are unbounded, can be explained by the well-known fact that the consensus protocol has a closed-loop eigenvalue at the origin (Olfati-Saber et al., 2007). Nevertheless, the boundedness of the control signals under such conditions is intriguing. Situations wherein some signals in the closed-loop system are bounded while some others are not normally indicate unstable pole-zero cancellations in the feedback loop (Zhou et al., 1996, Sec. 5.3). However, controller (2) is static and thus has no zeros.

1.2. Contribution

The example above suggests that a deeper inspection of the internal stability property could offer insight into the behavior of diffusively-coupled systems. The internal stability of any feedback interconnection requires the stability of all possible input/output relations in the system, see (Zhou et al., 1996, Skogestad and Postlethwaite, 2005). However, to the best of our knowledge, internal stability has not been explicitly studied in the context of diffusively-coupled architectures of MASs yet.

In this paper we show that diffusively-coupled systems of LTI (linear time-invariant) agents might not be internally stabilizable. Loosely speaking, this happens if the agents share common unstable dynamics, directions counting. This, for example, is always the case in a group of homogeneous unstable agents, like those discussed in (1.1).

When restricting the result to finite-dimensional agents, we also explain the mechanism behind the shown internal instability. It is caused by unstable cancellations in the cascade of the aggregate plant and a diffusive controller. Important is that these cancellations are caused not by controller zeros, but rather by an intrinsic spatial deficiency of the diffusively-coupled configuration. These cancellations are intrinsic to the diffusive structure and cannot be affected by controller dynamics. Consequently, the internal stability of feedback systems utilizing only relative measurements depends solely on the agent dynamics.

In addition to providing a rigorous analysis of the internal stability of diffusively-coupled systems, we show how the analysis is readily applied to common extensions found in the literature. In particular, we discuss more general symmetrically coupled multi-agent systems (i.e. not restricted to only diffusive coupling), asymmetric coupling (i.e. MASs over directed graphs), unstable systems with no closed-right-half plane poles, and MASs over time-varying networks. Numerous examples are also provided along the way to illustrate the main results.

The paper is organized as follows. The problem is set up in Section 2 and the main result is presented in Section 3, with several generalizations discussed in §2.2. Section 4 addresses the case of finite-dimensional agents, reformulating the main result in a more transparent form and revealing the underlying reason for the observed behavior. Concluding remarks are provided in Section 5. Two appendices collect definitions and technical results about coprime factorizations over $H_\infty$ and poles and zero directions of multivariable real-rational transfer functions.

Notation

The sets of integer, real, and complex numbers are $\mathbb{Z}$, $\mathbb{R}$, and $\mathbb{C}$, respectively, with subsets $\mathbb{N}_\nu := \{i \in \mathbb{Z} \mid 1 \leq i \leq \nu\}$, $\mathbb{C}_0 := \{s \in \mathbb{C} \mid \text{Re } s > 0\}$, and $\mathbb{C}_0 := \{s \in \mathbb{C} \mid \text{Re } s \geq 0\}$. By $I_\nu$ and $1_\nu$, we denote the $\nu \times \nu$ identity matrix and $\nu$-dimensional vector of ones, respectively. When the dimension is immaterial or clear from context, we use $I$ and $1$. The complex-conjugate transpose of a matrix $A$ is denoted by $A^\dagger$, the set of all its eigenvalues by spec$(A)$, and its minimal singular value by $\gamma(A)$. The notation $\text{diag}(A)$ stands for a block-diagonal matrix with diagonal elements $A_i$. The image (range) and kernel (null) spaces of a matrix $A$ are notated $\text{Im } A$ and ker $A$, respectively. Given two matrices $A$ and $B$, $A \otimes B$ denotes their Kronecker product.

By the stability of a system $G$ we understand its $L_2$-stability. It is known (Curtain and Zwart, 2020, §A.6.3) that a $p \times m$ LTI system is causal and stable iff its transfer function $G(s)$ belongs to $H_\infty^{p \times m}$, which is the space of holomorphic and bounded functions $C_0 \rightarrow C_\infty^{p \times m}$ (we write $H_\infty$ when the dimensions are clear). Given a real-rational transfer function $G(s)$, its McMillan degree is denoted by $\deg(G)$. By rank $G(s)$ we understand the normal rank of a function $G(s)$.

A digraph $G = (\mathcal{V}, \mathcal{E})$ consists of a vertex set $\mathcal{V}$ and an edge set $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$, see (Godsil and Royle, 2001) for more details. The (oriented) incidence matrix of $G$ is denoted by $E_G$ or simply $E$ when the association with a concrete graph is clear. It is a $|\mathcal{V}| \times |\mathcal{E}|$ matrix, whose $(i, j)$ entry is

$$[E_G]_{ij} = \begin{cases} 1 & \text{if vertex } i \text{ is the head of edge } j \\ -1 & \text{if vertex } i \text{ is the tail of edge } j \\ 0 & \text{if vertex } i \text{ does not belong to edge } j \end{cases}$$
Note that the construction of the incidence matrix implies that $1^T E_{\mathcal{G}} = 0$ for every $\mathcal{G}$.

### 2. Problem formulation

Consider $v$ continuous-time LTI agents $P_i$, each with $m$ inputs and $p$ outputs, who interact over a graph $\mathcal{G}$ with $v$ nodes and $\mu$ edges. In this formalism, agents $i$ and $j$ are neighbors, in the sense defined in the Introduction, if they are incident to the same edge.

A general diffusively-coupled MAS originated in (Arcak 2007), also known as the canonical cooperative control structure (Bullo 2022, Ch. 9), is presented in Fig. 2. It comprises the block-diagonal aggregate plant $P := \text{diag}(P_i)$ with $v$ blocks, a block-diagonal edge controller $K_e := \text{diag}(K_{e,j})$ with $\mu$ blocks, and pre- and post-processing based on the incidence matrix $E$ associated with $\mathcal{G}$. To describe the logic of this setup we may disregard the exogenous signals $d_x$ and $d_y$, which we refer to as disturbances. On the physical level they represent inevitable effects of the outside world on the controlled plant (agents). These signals are supposed to be bounded and independent of the signals generated by the controlled system. We introduce disturbances to define the notion of the internal stability for the system in Fig. 2, which is the focus point of this paper. Specifically, we say that this system is internally stable if the $2 \times 2$ operator connecting exogenous signals $d_x$ and $d_y$ with internal signals $u$ and $y$, i.e.

$$T_a : (d_y, d_x) \mapsto (y, u) \tag{5}$$

is well defined and stable, see (Georgiou and Smith, 1993, Sec. 4).

The general question of interest in this paper is under what conditions on the agents $P_i$ are there causal edge controllers $K_{e,j}$ internally stabilizing the diffusively-coupled system in Fig. 2? Note that the existence of edge controllers rendering the closed-loop operator well defined is obvious, just take $K_{e,j} = 0$ for all $j$. We shall thus focus on the stability of $T_a$.

Addressing the stability question in the most general, non-linear and time-varying, case might be overly technical. We thus limit our attention to the class of LTI plants and edge controllers, whose transfer functions belong to the quotient field of $H_{\infty}$, see (Curtain and Zwart, 2020, §A.7.1), which is a sufficiently general class. We further assume that

- \( \mathcal{A}_1 \): there are right coprime $M_i, N_i \in H_{\infty}$ and left coprime $M_i, N_i \in H_{\infty}$ such that $P_i = N_i M_i^{-1} = M_i^{-1} N_i$ for all $i$, where coprimeness is understood as the existence of Bézout coefficients in $H_{\infty}$, see Appendix A. The representation of $P_i$ above is known as its coprime factorization. We hereafter refer to the transfer functions $M_i(s)$ and $\tilde{M}_i(s)$ as the right and left denuminators of $P_i$, respectively, and the transfer functions $N_i(s)$ and $\tilde{N}_i(s)$ as its right and left numerator. Assumption \( \mathcal{A}_1 \) is practically nonrestrictive. It holds for all finite-dimensional agents with proper transfer functions and is equivalent to the stabilizability of $P_i$ by feedback for agents with transfer functions from the quotient field of $H_{\infty}$ (Smith, 1989). Thus, if an agent fails to satisfy \( \mathcal{A}_1 \) we cannot expect any MAS that includes it to be stabilizable by diffusive coupling.

**Remark 1.** We choose the application points of exogenous disturbances for the internal stability analysis to be at the points where the agents, $P$, are connected with the controller $K$ defined in (4). In this choice we follow the physical nature of the interconnection in Fig. 2, and think of separating the blocks $E \otimes I$ and $E^T \otimes I$ in the controller as merely a way to streamline the choice of the design parameters, which are the edge controllers in $K_e$. An alternative viewpoint is presented in Fig. 3 where all

\[
E = \begin{bmatrix}
1 & 0 \\
0 & 1 \\
-1 & -1
\end{bmatrix},
\]

in which case

\[
\tilde{y} = \begin{bmatrix}
y_1 - y_3 \\
y_2 - y_3
\end{bmatrix} \quad \text{and} \quad u = \begin{bmatrix}
\tilde{u}_1 \\
\tilde{u}_2
\end{bmatrix}.
\]

The consensus protocol (2) corresponds to the choice $K_e = -I$ in this case, as well as for any other choice of $\mathcal{G}$ and $v$.
fixed parts are regarded as the controlled plant,
\[ P_e := (E \otimes I_P)P(E \otimes I_m), \]
much inline with the generalized plant philosophy \cite[Sec. 3.8]{SkogestadPostlethwaite2005}, see e.g. \cite[(Zelazo and Mésbahi 2011a, Fig. 6)]{ZelazoMeso2011} or \cite[(Bullo 2022, E9.6)]{Bullo2022}. A natural definition of internal stability for it shall be based on the exogenous inputs \( \tilde{d}_y \) and \( \tilde{d}_u \), entering before and after the edge controller \( K_e \). This would change the results, see Remark \ref{rem:three} at the end of \S 3.1. Still, we believe that the configuration in Fig. \ref{fig:diffsys} is the right way to address the internal stability of MASs. After all, it is the agents who interact with the environment.

3. The main result

The main technical result of this work, whose proof is postponed to \S 3.1 is formulated as follows.

**Theorem 3.1.** No LTI \( K_{e,j} \) can internally stabilize the diffusively-coupled system in Fig. \ref{fig:diffsys} if there is a \( \lambda \in \mathcal{C}_0 \), common to all agents, such that
\[
\bigcap_{i=1}^{n} \ker \{M_i(\lambda)\}^T \neq \{0\} \tag{7a}
\]
or
\[
\bigcap_{i=1}^{n} \ker \tilde{M}_i(\lambda) \neq \{0\}. \tag{7b}
\]
where \( M_i \) and \( \tilde{M}_i \) are denominators in the coprime factorizations of \( P_i \) under \( \mathcal{A} \).

Theorem 3.1 formulated in terms of coprime factors of agents, might appear somewhat abstract and technical. This is a consequence of considering a fairly general class of LTI agents under the mild assumption \( \mathcal{A} \). We show in the next section that if the class of admissible agents is limited to finite-dimensional ones, then more insightful statements can be provided. Nevertheless, the formulation in Theorem 3.1 becomes substantially more intuitive in some frequently studied special cases.

The first of them is the case of homogeneous agents, which is perhaps the best studied situation.

**Corollary 3.2.** If the agents are homogeneous, i.e. \( P_i = P_0 \) for all \( i \in \mathbb{N}_0 \), and \( P_0(s) \) has at least one pole in \( \mathcal{C}_0 \), then no LTI \( K_{e,j} \) can internally stabilize the system in Fig. \ref{fig:diffsys}.

**Proof.** By Lemma \ref{lem:three} if \( \lambda \in \mathcal{C}_0 \) is a pole of \( P_0(s) \), then both \( M_0(\lambda) \) and \( \tilde{M}_0(\lambda) \) are singular, whence the result follows. \( \square \)

This result readily applies to the problem studied in \S 1.1. The agents in \( \mathcal{A} \) are homogeneous and \( P_0(s) = 1/s \) has an unstable pole at the origin. Corollary \ref{cor:three} then agrees with the conclusion of \S 1.1 that the closed-loop system is not internally stable.

Another particular case for which the formulation is simplified is a MAS with SISO agents.

**Corollary 3.3.** If the agents are SISO and all have a pole at the same \( \lambda \in \mathcal{C}_0 \), regardless of multiplicities, then no LTI \( K_{e,j} \) can internally stabilize the diffusively-coupled system in Fig. \ref{fig:diffsys}.

**Proof.** By Lemma \ref{lem:three} in this case \( M_i(\lambda) = \tilde{M}_i(\lambda) = 0 \) for all \( i \in \mathbb{N}_0 \), whence the result follows. \( \square \)

A consequence of Corollary 3.3 is that the consensus protocol, as well as any other diffusively-coupled control laws, cannot internally stabilize a group of SISO agents if all of them contain an integral action. This result is reminiscent of that by \cite{Wieland2011} that states that a common internal model is a necessary condition for a diffusively-coupled system to synchronize their state trajectories. It highlights a contradiction or trade-off of sorts, where on the one hand, a common pole at the origin among agents is required for synchronization, and on the other hand, this common (unstable) pole is precisely the cause for lack of internal stability.

3.1. Proof of Theorem 3.1

We are now prepared to prove Theorem 3.1. Only the statement about the right coprime factor, i.e. \ref{eq:three} is proved. The proof of \ref{eq:seven} follows by dual arguments.

The proof requires a technical result of Fuhrmann \cite{Fuhrmann1968}, known as the matrix corona theorem, see also the proof of \cite[Prop. 11]{GeorgiouSmith1993} for a closer formulation.

**Lemma 3.4.** If \( G \in H_\infty^{\mathbb{R}^{nxn}} \), then
\[
G^{-1} \in H_\infty \iff \inf_{s \in \mathbb{C}_0} \Re(G(s)) > 0.
\]

It is readily seen that \( M_P := \text{diag}\{M_i\} \) and \( N_P := \text{diag}\{N_i\} \) are right coprime factors of \( P = \text{diag}\{P_i\} \). Because any internally stabilizing \( K \) in \( \mathcal{A} \) is in effect stabilized by the plant, we only need to consider edge controllers for which \( K \) admits coprime factorizations over \( H_\infty \). So let \( K = N_K M_K^{-1} \) for right coprime \( M_K, N_K \in H_\infty \) by \ref{lem:four}.

\[
N_K(s) = (E \otimes I_m)K_c(s)(E^T \otimes I_P)M_K(s).
\]

Because \( E^T \otimes E = 0 \), we have that \( (1^T \otimes I_m)(E \otimes I_m) = 0 \) as well and, hence, \( (1^T \otimes I_m)N_K(s) = 0 \) for all \( s \) at which \( K_c(s) \) is finite. But \( K_c(s) \) is in the quotient field of \( H_\infty \), meaning that the denominators of its entries are holomorphic in \( \mathbb{C}_0 \) and, by \cite[Thm. 10.18]{Rudin1987}, may have at most countable number of isolated zeros. As such, we can always find a region in \( \mathbb{C}_0 \) in which \( (1^T \otimes I_m)N_K(s) = 0 \). But the latter implies that
\[
(1^T \otimes I_m)N_K = 0,
\]
by the same (Rudin, 1987, Thm. 10.18). Now, return to the system in Fig. 2. It is readily verified that the closed-loop system $T_4$ in (5) reads

$$T_4 = \begin{bmatrix} I/K \end{bmatrix} (I - PK)^{-1} \begin{bmatrix} I & P \end{bmatrix} = \begin{bmatrix} S & T_0 \\ T_c & T \end{bmatrix},$$

(8)

where the blocks of $T_4$ are the four fundamental closed-loop transfer functions. Straightforward algebra yields that

$$T_4 = \begin{bmatrix} M_K & 0 \\ N_K & 0 \end{bmatrix}^{-1} \begin{bmatrix} M_K & -N_P \\ -N_K & M_P \end{bmatrix}.$$

(9)

This is a right coprime factorization of $T_4$, as attested by the Bézout equality (cf. (A.11)).

$$\begin{bmatrix} \tilde{M}_P & \tilde{N}_P \\ -Y_P & X_P \end{bmatrix} \begin{bmatrix} M_K & -N_P \\ -N_K & M_P \end{bmatrix} + \begin{bmatrix} X_K - \tilde{M}_P & Y_K + \tilde{N}_P \\ Y_P & X_P \end{bmatrix} \begin{bmatrix} M_K & 0 \\ N_K & 0 \end{bmatrix} = I,$$

where $\tilde{M}_P := \text{diag}(\tilde{M}_1)$ and $\tilde{N}_P := \text{diag}(\tilde{N}_1)$. By Lemma 3.1 $T_4$ is stable if and only if

$$\begin{bmatrix} M_K & -N_P \\ -N_K & M_P \end{bmatrix}^{-1} \in H_{\infty},$$

(10)

or

$$\inf_{s \in \mathbb{C}_0} \gamma^2 \left( \begin{bmatrix} M_K(s) & -N_P(s) \\ -N_K(s) & M_P(s) \end{bmatrix} \right) > 0,$$

(11)

by Lemma 3.4. But (7a) implies that there is $\nu \neq 0$ such that $\nu^T M_1(\lambda) = 0$ for all $i$, or, equivalently, $\nu^T (I \otimes \nu)^T M_1(\lambda) = 0$. Taking into account that $(I \otimes v)^T N_1 = v^T (I \otimes I_2)^T N_1 = 0$, we end up with

$$\begin{bmatrix} 0 & (1 \otimes v)^T \end{bmatrix} \begin{bmatrix} M_K(\lambda) & -N_1(\lambda) \\ -N_K(\lambda) & M_P(\lambda) \end{bmatrix} = 0,$$

(12)

which violates (11). We thus have that if (7a) holds, then there is no $K_e$ that internally stabilizes the system in Fig. 2.

3.2. Generalizations

Some possible generalizations of the result of Theorem 3.1 are outlined below.

3.2.1. Asymmetric coupling

Some MAS problems consider a directed interaction graph, making the notion of neighboring agents asymmetric. Controllers under such constrains are no longer diffusive in the sense discussed in Section 2. Still, a variant of Theorem 3.1 may apply.

For example, let an edge going from node $i$ to node $j$ indicate that the $i$th agent has access to $y_j - y_i$. The existence of the edge $(i, j)$ does not imply that there is also the edge $(j, i)$. It is evident that the controller outlined in Fig. 2 and 3 can no longer provide an appropriate distributed controller since, as discussed in Section 2, it sums up all the edge correction terms connected to each corresponding node. Nevertheless, several notable MAS control architectures over directed graphs still admit a decomposition similar to that of (4). Consider again the classic consensus protocol. It can be adapted to accommodate directed graphs by replacing the symmetric Laplacian, $L = EE^T$, with a directed counterpart such as the out-degree Laplacian $L_{out}$ (Bullo, 2022, Sec. 7.3). By defining an auxiliary matrix,

$$[B_{out}]_{ij} = \begin{cases} 1 & \text{if vertex } i \text{ is the head of edge } j \\ 0 & \text{otherwise} \end{cases},$$

the directed out-degree Laplacian can be represented by the product $L_{out} = B_{out}E^T$. This suggests that a controller of the form

$$K_{out} := (B_{out} \otimes I_n)K_e(E^T \otimes I_p),$$

(13)

can be used to represent various control laws over directed graphs. For example setting $K_e = -I$ results in the aforementioned directed consensus protocol, while picking $K_e = I_v \otimes K$ for some gain $K$ yields the synchronizing controllers discussed in (Bullo, 2022, Sec. 8.4).

The controller structure in (13) mirrors that in (4). If (7b) holds, then the proof of Theorem 3.1 applies verbatim to any MAS controlled by it. However, this is not the case for (7a), implying that some systems may be stabilizable only if the graph is directed, as illustrated in the following example.

Example 1. Consider a system of $v = 3$ first-order agents

$$P_1(s) = \begin{bmatrix} 1 & 0 \\ 1/s & 1 \end{bmatrix} \quad \text{and} \quad P_2(s) = P_3(s) = \begin{bmatrix} 1/s & 0 \\ 1 & 1 \end{bmatrix}.$$

Assume that their connectivity is represented by the directed cycle graph, which has three directed edges $(1, 2), (2, 3)$, and $(3, 1)$. This system can be described by (13) with

$$E = \begin{bmatrix} 1 & 0 & -1 \\ -1 & 1 & 0 \\ 0 & -1 & 1 \end{bmatrix}, \quad B_{out} = I_3,$$

and arbitrary block-diagonal edge controllers. It is then a matter of standard algebra to verify that these plants admit denominators

$$\tilde{M}_1(s) = \begin{bmatrix} 1 & 0 \\ 0 & s/(s + 1) \end{bmatrix}$$

and

$$\tilde{M}_2(s) = \tilde{M}_3(s) = \begin{bmatrix} 0 & 0 \\ s/(s + 1) & 1 \end{bmatrix} = M_i(s), \quad \forall i \in \{1, 2, 3\}.$$
Of course, following a similar procedure we may define the analogous $K_{in}$ (corresponding for example to the in-degree directed consensus protocol) and consider only condition (7a), then again the proof holds unchanged.

**Remark 2.** The stabilizability of control architectures over directed graphs may nevertheless still require checking both conditions of Theorem 3.1. This thesis is based on an interpretation of the edge controller (13) as (dynamic) edge weights of the directed graph. A directed graph is called *weight balanced* if the accumulated weights of incoming and outgoing edges are equal for each node. It is known (Mesbah and Egerstedt 2010) Thm. 3.17 that the consensus protocol for integrator agents can reach an average agreement, i.e. $x_i(t) \rightarrow (1/n)\int x(0)$ for all $i$, iff the underlying digraph is weight balanced and weakly connected. A key property to prove this result is that the Laplacian of a weight-balanced digraph, $L_{out}$, satisfies $kerL_{out} = kerL_{out}^{*} = \text{Im}I$. Viewed within the context of Theorem 3.1, this implies that if edge controllers in (13) are chosen such that digraph is weight balanced, then both conditions of (7) must be checked anyway.

3.2.2. Arbitrary symmetric coupling

The result of Theorem 3.1 still holds if the incidence matrix is replaced with a different coupling matrix, say $F \in \mathbb{R}^{n \times n}$, as long as there is a vector $0 \neq v \in \mathbb{R}^{n}$ such that $v^{T}F = 0$. Such generalizations of a MAS were previously discussed in Belabbas et al. (2021), but are also included in works considering, for example, distributed function calculation in MAS (Sundaram and Hadjicostis, 2008).

3.2.3. Unstable systems with no poles in $\mathbb{C}_0$

It might happen that $P_i \not\in H_\infty$ not because of poles, or other singularities, in $\mathbb{C}_0$. For example, $P_i(s) = s/(s + 1 + s e^{-\tau})$ has no singularities in $\mathbb{C}_0$, but nonetheless does not belong to $H_\infty$, see Partington and Bonnet (2004). The proof still applies in this case, and all we need to replace (12) with the assumption that there is a sequence $\{\lambda_i\}$ in $\mathbb{C}_0$ such that $\inf_{\lambda_i} v^{T}M_1(\lambda_i) = 0$, or its dual version, holds for all $i \in \mathbb{N}_n$ and some $v \neq 0$.

3.2.4. Time-varying $K$

The main result also extends to the case of time-varying controllers. This is particularly relevant for varying interconnection topologies, i.e. those where $E_{\bar{G}(t)} = E(t)$ is the incidence matrix of the time-varying graph $\bar{G}(t)$. Still, the condition $F^{T}E(t)$ holds for any topology, rendering the denominator in (9) not stably invertible. We can then use Verma (1988) Theorem (i) to show that under no choice of $K_{in}$ the system is stabilizable, at least in the finite-dimensional case, whenever either one of the conditions in (7) holds.

4. Finite-dimensional agents

If the agents $P_i$ are finite dimensional, the result of the previous section can be reformulated in a more insightful way. This is due to the ultimate connection between stability and pole locations, as well as clear definitions of cancellations in this case. So we proceed with assuming that all transfer functions $P_i(s)$ are real rational and proper ($\mathbb{C}_0$ always holds then).

Let $\text{pdir}_i(G, \lambda)$ and $\text{pdir}_o(G, \lambda)$ denote input and output direction of a pole $\lambda$ in $G(s)$, see Appendix B for details and other related definitions. The result below reformulates the conditions of Theorem 3.1 via pole directions of agents.

**Proposition 4.1.** If $P_i(s)$ are real rational and proper, then (7a) and (7b) are equivalent to the existence of $A \in \mathbb{C}_0$ such that

$$\bigcap_{i=1}^{n} \text{pdir}_i(P_i, \lambda) \neq \{0\}$$

and

$$\bigcap_{i=1}^{n} \text{pdir}_o(P_i, \lambda) \neq \{0\},$$

respectively.

Proof. Because $A \in \mathbb{C}_0$ is not a pole of $M_i(s)$, Lemma B.2 applies and (7a) reads $\bigcap_{i=1}^{n} \text{pdir}_i(M_i, \lambda) \neq \{0\}$. Then (14a) follows by Lemma B.3. The proof for (14b) is similar.

In other words, for the system in Fig. 2 to not be stabilizable, the agents should not only have a common unstable pole, but also a common nontrivial direction of such a pole. Directions are obviously matched in the homogeneous and SISO cases addressed in Corollaries 3.2 and 3.3, respectively. But the MIMO heterogeneous case may be less trivial.

**Example 2.** Consider a system with $n = 2$ first-order agents

$$P_1(s) = \begin{bmatrix} 1/s & 0 \\ 0 & 1 \end{bmatrix} \quad \text{and} \quad P_2(s) = \begin{bmatrix} 1/\alpha & 1/\beta \\ 1/\alpha & 1/\beta \end{bmatrix}.$$ 

Directions of their pole at the origin are $\text{pdir}(P_1, 0) = \text{pdir}_i(P_1, 0) = \text{Im} \begin{bmatrix} 1/\alpha \\ 1/\beta \end{bmatrix}$, and $\text{pdir}(P_2, 0) = \text{Im} \begin{bmatrix} 1/\alpha \\ 1/\beta \end{bmatrix}$.

There are nontrivial intersections between input and output directions of the agents if and only if $\beta = 0$ and $\alpha = 0$, respectively. The incidence matrix is $E = \begin{bmatrix} 1/\alpha & -1 \end{bmatrix}$ in this case. Choose the edge controller (there is only one edge in this example) as

$$K_e(s) = \begin{bmatrix} (\alpha - \beta) & -\alpha \\ \beta & 0 \end{bmatrix}.$$ 

The closed-loop characteristic polynomial, understood as the lowest common denominator of elements of $T_e(s)$ in (8), is then $(s + \alpha^2)(s + \beta^2)$. Thus, the closed-loop system is stable unless $\alpha = 0$ or $\beta = 0$, which agrees with (14).

Also worth emphasizing is that conditions (14a) and (14b) might not be equivalent for MIMO agents, as illustrated by the example below.
Example 3. Return to the system studied in Example 1. Directions associated with the (unstable) pole at the origin are
\[
p_{\text{dir}}(P_i, 0) = \text{Im} \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad \forall i \in \mathbb{N}_3
\]
but
\[
p_{\text{dir}}(P_1, 0) = \text{Im} \begin{bmatrix} 0 \\ 1 \end{bmatrix} \neq \text{Im} \begin{bmatrix} 1 \\ 0 \end{bmatrix} = p_{\text{dir}}(P_2, 0).
\]
Thus, in this case (14a) holds, whereas (14b) does not. This agrees with what we saw in Example 1 with respect to conditions 7.

Another outcome of the finite dimensionality is that the formulation of Corollary 3.2 can be strengthened to an “if and only if” statement.

Corollary 4.2. If the agents are homogeneous, i.e. \( P_i = P_0 \) for all \( i \in \mathbb{N}_n \), and \( P_0(s) \) is real rational and proper, then an LTI \( K_{e,j} \) can internally stabilize the diffusively-coupled system in Fig. 2 if and only if \( P_0 \) is stable.

Proof. If \( P_0 \) is unstable, then it has a pole in \( \mathbb{C}_0 \) and Corollary 3.2 applies. If \( P_0 \) is stable, \( K_e = 0 \) does the job. \( \square \)

One should be careful not to conclude from the proof of Corollary 4.2 that only \( K_e = 0 \) can be used to guarantee internal stability. The case of \( K_e = 0 \) effectively decouples all the agents leading only to a “trivial” coordination (i.e. all agents converge to the origin). One can design edge controllers with additional external inputs to drive the relative states \( \bar{y} \) to non-trivial solutions using the methods, for example, described in [Sharf and Zelazo, 2017]. For non-trivial agreement among the agents, the use of an unstable edge controller is possible provided that an appropriately defined external input is fed into the system at the point \( d_\lambda \) in Fig. 2.

4.1. Diffusive control laws and unstable cancellations

The formulation of Proposition 4.1 is more intuitive than that of Theorem 3.1. Still, neither of them explains why no edge controller can stabilize the system in Fig. 2 if agents share common unstable dynamics, directions counted. In this part we aim at offering explanations. We argue that a key property to this end is intrinsic unstable cancellations between the plant and the controller.

The cascade (series) interconnection \( G_2G_1 \) has cancellations if \( \deg(G_2G_1) < \deg(G_1) + \deg(G_2) \). In other words, cancellations mean that some parts of the dynamics (modes) of either factor disappear in the cascade. Specifically, we say that a pole of \( G_1(s) \) and/or \( G_2(s) \) is canceled if its multiplicity in \( G_2(s)G_1(s) \) is smaller than the sum of its multiplicities in \( G_1(s) \) and \( G_2(s) \). Cancellations in the SISO case are always caused by the presence of zeros of \( G_1(s) \) at the locations of poles of \( G_2(s) \), or vice versa. As such, they are termed pole-zero cancellations. The situation is more complex in the MIMO case. For example, let
\[
G_1(s) = \frac{1}{s} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \quad \text{and} \quad G_2(s) = \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix},
\]
with \( \deg(G_1) = 2 \) (two poles at the origin) and \( \deg(G_2) = 0 \) (no poles). The system \( G_2 \) is static and thus has no zeros either. Nevertheless, the transfer function
\[
G_2(s)G_1(s) = \frac{1}{s} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}
\]
is first order, meaning that one of the poles of \( G_1(s) \) is canceled. Such cancellations, brought on by the normal rank deficiency of \( G_2(s) \), are a lesser-known phenomenon.

The result below, proved in §4.2, states that such cancellations are present between the plant and the controller in Fig. 2 whenever the conditions of Proposition 4.1 hold.

Proposition 4.3. Let \( P(s) \) and \( K_e(s) \) be real rational and proper and let \( \lambda \in \mathbb{C}_0 \) be a pole of \( P(s) \).

i) If (14a) holds, then \( \lambda \) is canceled in \( P(s)K_e(s) \).

ii) If (14b) holds, then \( \lambda \) is canceled in \( K_e(s)P(s) \).

Unstable pole-zero cancellations between a plant and a controller are a consensual taboo in feedback control. Textbooks treat them as a kind of a cardinal sin, which shall be avoided at all costs. The reason is that canceled dynamics do not really disappear. For example, poles of a SISO plant \( P(s) \) canceled by zeros of a controller \( K(s) \) always show up in the closed-loop disturbance sensitivity \( T_d(s) \), see (5). This is the very reason to require internal stability. Unstable cancellations due to deficient normal rank are less common and less studied. Nevertheless, they cause some repercussions. Namely, canceled dynamics show up in at least one closed-loop relation, rendering the system prone to the effect of exogenous signals.

Assume, for example, that condition (14a), or (7a), holds for some \( \lambda \in \mathbb{C}_0 \). It follows from the proof of Theorem 3.1 that there is then \( v \neq 0 \) such that (12) holds. Therefore,
\[
\begin{bmatrix} 0 \\ 1 \otimes v \end{bmatrix} \in \text{zd}\text{dir}_o \begin{bmatrix} M_K & -N_P \\ -N_K & M_P \end{bmatrix}, \lambda = \text{pdir}_e(T_\lambda, \lambda)
\]
where the equality follows by Lemma 3.3 and the fact that the factors in (19) are right coprime. By Lemma 3.1 and (8)
\[
T_d(s) \begin{bmatrix} 0 \\ 1 \otimes v \end{bmatrix} = \begin{bmatrix} T_d(s) \\ T(s) \end{bmatrix} (1 \otimes v)
\]
has an unstable pole at \( s = \lambda \). In other words, there is a load disturbance \( d_u \) in Fig. 2 such that either \( y \) or \( u \) is unbounded. Likewise, it can be shown that if (14b) holds, then \( \left[ S \ T_\lambda \right] \not\in \mathbb{H}_\infty, \text{i.e. } d_u \text{ or/and } d_y \text{ might cause an unbounded } y \). This explains why the consensus protocol in (11) has an unstable load disturbance response.

It can be shown that if the consensus discussed in §1.1 can be attained, then all components of \( T_d \) but \( T_d \) are stable, whereas \( T_d(s) \) has a pole at the origin. This agrees with the situation in SISO pole-zero cancellations discussed above. However, \( T_\lambda \) is not necessarily unstable in a general MIMO case if either of the conditions in (13) holds. The example below illustrates a different scenario.
Consider a system with \( \nu = 2 \) agents

\[
P_1(s) = \begin{bmatrix} s/(s+1) & 0 \\ 1/s & 1 \end{bmatrix} \quad \text{and} \quad P_2(s) = \begin{bmatrix} 1/s & 0 \\ 1 & s/(s+1) \end{bmatrix}
\]

(both are second order). In this case there is only one edge. Select

\[
K_c(s) = K_{c,1}(s) = \frac{1}{3} \begin{bmatrix} 1 & 0 \\ 0 & 2/s \end{bmatrix}.
\]

It is then a matter of routine calculations to see that \( S, T_d, \) and \( T_c \) are stable, each having \((s+2)(2s+1)^2(3s+1)\) as the lowest common denominator of its entries. However, \( T(s) \) has a pole at the origin in addition, rendering the whole \( T_d \) unstable.

Moreover, it may even happen that canceled dynamics of \( P \) are not excited by the (load) disturbance \( d_u \), but rather only by \( d_y \).

Consider a system with \( \nu = 2 \) agents, yet again, now with the second order

\[
P_1(s) = \begin{bmatrix} s/(s+1) & 1/s \\ 0 & 1 \end{bmatrix} \quad \text{and} \quad P_2(s) = \begin{bmatrix} 1/s & 1 \\ 0 & s/(s+1) \end{bmatrix}
\]

and the edge controller from Example 4. It can be calculated that in this case \( T, T_d, \) and \( T_c \) are stable, each having \((s+2)(2s+1)^2(3s+1)\) as the lowest common denominator of its entries. The sensitivity \( S(s) \) has an additional pole at the origin. This implies that the responses to \( d_u \) are all stable, whereas the response of \( y \) to \( d_y \) is unstable.

Remark 3. Stabilizability conditions for the setup in Fig. 3 would be substantially different from those in Theorem 3.1 or Proposition 4.1. If we consider the class of LTI edge controllers \( K_e \), then the stabilizability problem boils down to the question of existing decentralized fixed modes (DFMs) in \( \mathcal{P}_e \) defined by 6. If controllers are allowed to be periodically time-varying, then this condition is not restrictive. However, this analysis has a snag in that the very construction of \( \mathcal{P}_e \) might have unstable cancellations. For example, return to the case of \( \nu = 3 \) integrator agents with an indirect star interconnection graph discussed in Section 2. In this case \( P(s) = (1/s)I_3 \) has three poles at the origin, whereas

\[
P_e(s) = \begin{bmatrix} 1 & 0 & -1 \\ 0 & 1 & -1 \end{bmatrix} \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} = \frac{1}{s} \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix}
\]

is a second-order transfer function. This \( P_e \) is easily stabilizable by decentralized edge controllers, e.g. by \( K_e = -I_2 \). But this controller cannot see the canceled unstable mode, which remains a part of the closed-loop system.

4.2. Proof of Proposition 4.1

Bring in minimal realizations

\[
P_1(s) = \begin{bmatrix} A_1 & B_1 \\ C_1 & D_1 \end{bmatrix} \quad \text{and} \quad K(s) = \begin{bmatrix} A_K & B_K \\ C_K & D_K \end{bmatrix}
\]

so the realization

\[
P(s) = \begin{bmatrix} A_P & B_P \\ C_P & D_P \end{bmatrix} \coloneqq \begin{bmatrix} \text{diag}(A_e) & \text{diag}(B_1) \\ \text{diag}(C_e) & \text{diag}(D_1) \end{bmatrix}
\]

is also minimal. To prove the first item of the Proposition it is then sufficient to show that \( \lambda \) is an uncontrollable mode of

\[
P(s)K(s) = \begin{bmatrix} A_K & 0 \\ B_P C_K & A_P \end{bmatrix} = \begin{bmatrix} B_K \\ D_P C_K & C_P \end{bmatrix}
\]

To this end, note that 3 implies \((1 \otimes I)^T [C_K \quad D_K] = 0\) and condition 14(a) is equivalent to the existence of \( 0 \neq v \in \mathbb{C}^m \) such that \( v^T \eta_r \) for some \( \eta_r \) such that \( \eta_r^T(\lambda I - A_r) = 0 \). The latter is equivalent to the existence of \( \eta \neq 0 \) such that

\[
\eta^T(\lambda I - A_P) = 0 \quad \text{and} \quad \eta^T B_P = (1 \otimes v)^T
\]

for some \( v \neq 0 \). Therefore,

\[
\begin{bmatrix} 0 & \eta^T \\ \eta^T & (1 \otimes I)^T \end{bmatrix} \begin{bmatrix} A_K - \lambda I & 0 \\ B_P C_K & A_P - \lambda I \end{bmatrix} = \begin{bmatrix} B_K \\ D_P C_K & C_P \end{bmatrix} = 0
\]

and the PBH test for the realization of \( PK \) fails for the mode at \( \lambda \), proving the first item. The second item follows by similar arguments. □

5. Concluding remarks

In this paper we have studied the internal stability of multi-agent systems controlled by diffusively coupled laws. We have argued that internal stability, with entry points of exogenous signals at the connections between the agents and the controller, is a vital property in multi-agent systems and have proved that it can never be attained if the agents share common unstable dynamics, directions counted. In particular, this class always includes the case of homogeneous unstable agents or heterogeneous SISO agents with a common unstable pole, like an integral action. We have shown that the underlying reason for the lack of stabilizability is intrinsic cancellations of aligned unstable dynamics of agents by the diffusive coupling mechanism.

An immediate outcome of the proposed analysis is that the uniformity must be broken in the control of unstable multi-agent systems. This is the underlying reason behind several of the different assumptions mentioned in Section 3. Introducing a leader, or “virtual” agent, can potentially break the common instability, while permitting non-relative feedback either locally stabilize the agents or again, break the uniformity.

of the subject can be found in [Vidyasagar, 1985].

Functions \( M \in H^\infty_{\text{mult}} \) and \( N \in H^\infty_{\text{all}} \) are said to be right coprime if there are \( \bar{X} \in H^\infty_{\text{all}} \) and \( \bar{Y} \in H^\infty_{\text{all}} \) (Bézout coefficients) such that

\[
XM + YN = I_n. \tag{A.1a}
\]

Functions \( \bar{M} \in H^\infty_{\text{all}} \) and \( \bar{N} \in H^\infty_{\text{mult}} \) are said to be left coprime if there are \( \bar{X} \in H^\infty_{\text{all}} \) and \( \bar{Y} \in H^\infty_{\text{all}} \) such that

\[
\bar{M} \bar{X} + \bar{N} \bar{Y} = I_n. \tag{A.1b}
\]

A transfer function \( G(s) \) is said to have coprime factorizations over \( H_\infty \) if there are right coprime \( M_G, N_G \in H_\infty \) and left coprime \( \bar{M}_G, \bar{N}_G \in H_\infty \), known as right and left coprime factors of \( G \), respectively, such that

\[
G = N_G M_G^{-1} = \bar{M}_G^{-1} \bar{N}_G. \tag{A.2}
\]

Coprime factors are unique up to post- or pre-multiplication by bi-stable transfer functions for right and left factors, respectively.

**Lemma A.1.** If \( G(s) \) has coprime factorizations, then

\[
G(s) \in H_\infty \iff M_G^{-1} \in H_\infty \iff \bar{M}_G^{-1} \in H_\infty.
\]

**Proof.** The “if” part of the first equivalence relation is immediate from (A.2). Its “only if” part follows from rewriting the Bézout equality (A.1a) as \( M_{G}^{-1} = X_{G} + Y_{G} G \). The second relation follows by similar arguments. \( \square \)

**Lemma A.2.** Let \( G(s) \) have coprime factorizations. If \( \lambda \in \mathbb{C}_0 \) is a pole of \( G(s) \), then \( M_G(\lambda) \) and \( \bar{M}_G(\lambda) \) are singular.

**Proof.** Because \( \lambda \in \mathbb{C}_0 \), the singularity of \( M_G(\lambda) \) or \( \bar{M}_G(\lambda) \) does not depend on concrete factorizations taken. If \( M_G(\lambda) \) is nonsingular, then \( N_G(\lambda) M_G(\lambda)^{-1} \) is bounded, which implies that \( \lambda \) cannot be a pole of \( G(s) \). The proof for \( \bar{M}_G \) is similar. \( \square \)

**Appendix B. Poles, zeros, and their directions**

This Appendix collects some definitions and facts on poles, zeros, and their directions for MIMO transfer functions. More details can be found in [Skogestad and Postlethwaite, 2005], although we use slightly different definitions of directions (spaces, rather than vectors), in line with [Mirkin, 2019].

Let \( G \) be a finite-dimensional LTI system having a proper transfer function \( G(s) \). The system \( G \) has a state-space realization

\[
G(s) = \begin{bmatrix} A & B \\ C & D \end{bmatrix} = D + C(sI - A)^{-1}B. \tag{B.1}
\]

The eigenvalues of \( A \) are known as poles of the realization \( B.1 \). The set of all realization poles, multiplicities counted, coincides with that of the poles of the transfer function \( G(s) \) if and only if the realization is minimal. **Invariant zeros** of the realization \( B.1 \) are defined as the points \( \lambda \in \mathbb{C} \) at which

\[
\operatorname{rank} \begin{bmatrix} A - \lambda I & B \\ C & D \end{bmatrix} < \operatorname{rank} \begin{bmatrix} A - sI & B \\ C & D \end{bmatrix}
\]
(the matrix polynomial of \( s \) in the right-hand side is dubbed the Rosenbrock system matrix). The set of all invariant zeros comprises transmission zeros of the transfer function \( G(s) \) and hidden modes of realization \((\ref{eq:rosenbrock})\).

Poles and zeros have (spatial) directions for MIMO systems. Assume through the rest of this Appendix that the realization in \((\ref{eq:rosenbrock})\) is minimal. By input and output directions of a realization pole \( \lambda \) of \((\ref{eq:rosenbrock})\), we understand the subspaces

\[
p\dir_\text{i}(G, \lambda) := B^\top \ker(\lambda I - A)^\top \subset \mathbb{C}^m \tag{B.2a}
\]

and

\[
p\dir_\text{o}(G, \lambda) := C \ker(\lambda I - A) \subset \mathbb{C}^p, \tag{B.2b}
\]

respectively. If \( \lambda \) is not a pole of \( G(s) \), then both definitions in \((\ref{eq:rosenbrock})\) result in the trivial subspace \( \{0\} \).

**Lemma B.1.** If \( \lambda \in \mathbb{C} \) is a pole of \( G(s) \), then

i) \( \lambda \) is a pole of \( G(s)v \) whenever \( 0 \neq v \in p\dir_\text{i}(G, \lambda) \).

ii) \( \lambda \) is a pole of \( v^\top G(s) \) whenever \( 0 \neq v \in p\dir_\text{o}(G, \lambda) \).

**Proof.** Bring in a minimal realization of \( G \) as in \((\ref{eq:rosenbrock})\). If \((A, B)\) is controllable, then every eigenvalue of \( A \) is a pole of \( G(s)v \), by the observability of \((C, A)\). If \((A, B)\) is uncontrollable, without loss of generality we may assume that

\[
(A, B) = \begin{bmatrix} A_c & A_{12} \\ 0 & A_e \end{bmatrix}, \begin{bmatrix} B_c \\ B_e \end{bmatrix}
\]

with controllable \((A_c, B_c v)\) and \( B_e v = 0 \). In this case \( \lambda \) is not a pole of \( G(s)v \) iff \( \lambda \notin \text{spec}(A_c) \). So assume that \( \lambda \notin \text{spec}(A_c) \), which implies that \( \lambda \in \text{spec}(A_e) \) and that

\[
B^\top \ker(\lambda I - A)^\top \subset \begin{bmatrix} B_c^\top \\ B_e^\top \end{bmatrix} \ker \begin{bmatrix} 0 & I \end{bmatrix} = \ker B_e^\top.
\]

But then \( v \in p\dir_\text{i}(G, \lambda) \implies v \in \ker B_e^\top = (\ker B_c)^\perp \), which contradicts the condition \( B_c v = 0 \). Hence, \( \lambda \) must be a pole of \( G(s)v \). The second item follows by similar arguments. \( \square \)

Input and output directions of an invariant zero \( \lambda \) are defined as

\[
p\dir_\text{i}(G, \lambda) := \begin{bmatrix} 0 & I_m \end{bmatrix} \ker \begin{bmatrix} A - \lambda I \\ C \end{bmatrix} \subset \mathbb{C}^m \tag{B.3a}
\]

and

\[
p\dir_\text{o}(G, \lambda) := \begin{bmatrix} 0 & I_p \end{bmatrix} \ker \begin{bmatrix} A - \lambda I \\ C \end{bmatrix}^\top \subset \mathbb{C}^p, \tag{B.3b}
\]

respectively. With some abuse of notation we use the definitions in \((\ref{eq:rosenbrock})\) also if \( \lambda \) is not an invariant zero of \((\ref{eq:rosenbrock})\), but the normal rank of \( G(s) \) is deficient. For example, in our notation

\[
p\dir_\text{i} \left( \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}, \lambda \right) = p\dir_\text{o} \left( \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}, \lambda \right) = \ker 1_2
\]

for all \( \lambda \in \mathbb{C} \). In such situations directions are understood as normal null spaces.

**Lemma B.2.** If \( \lambda \notin \text{spec}(A) \), then it is an invariant zero of \( G \) iff \( \text{rank} G(\lambda) < \text{rank} G(s) \) and

\[
p\dir_\text{i}(G, \lambda) = \ker G(\lambda) \text{ and } p\dir_\text{o}(G, \lambda) = \ker [G(\lambda)]^\top.
\]

**Proof.** Follows from the relations

\[
\begin{bmatrix} A - \lambda I & B \\ C & D \end{bmatrix} = \begin{bmatrix} A - \lambda I & 0 \\ C & G(\lambda) \end{bmatrix} \begin{bmatrix} I & (A - \lambda I)^{-1} B \\ 0 & I \end{bmatrix} = \begin{bmatrix} I & 0 \\ C(A - \lambda I)^{-1} & I \end{bmatrix} \begin{bmatrix} A - \lambda I & B \\ 0 & G(\lambda) \end{bmatrix}
\]

and the assumed invertibility of \( A - \lambda I \). \( \square \)

**Lemma B.3.** If \( \lambda \in \mathbb{C}_0 \), then it is a pole of \( G(s) \) if and only if it is a zero of the denominators \( M_G(s) \) and \( \hat{M}_G(s) \) of its coprime factorizations. Moreover,

\[
p\dir_\text{i}(G, \lambda) = p\dir_\text{o}(M_G, \lambda) \text{ and } \ p\dir_\text{o}(G, \lambda) = \text{zdri}(\hat{M}_G, \lambda)
\]

in this case.

**Proof.** Follows by \cite{mirkin2019}. Prop. 4.16 and the fact that a pole of \( G(s) \) in \( \mathbb{C}_0 \) is a zero of all possible denominators. \( \square \)
